This was broadly the state of physical science when Davy appeared upon the scene. Black and Cavendish were elderly men whose active work was over, and Priestley was ending his days in a distant land. England was at war with France, and there were no chemists of great note in the Germany of that day. This was also long antecedent to the time when chemical and physical laboratories for instruction existed in the universities or elsewhere, and the young Davy owed his introduction to physical science and his opportunities for study, as so many of the past generations of chemists and "natural philosophers" have done, to his association with medicine. Born in Penzance in 1778, he was apprenticed, at the age of seventeen, to an apothecary and surgeon practising in that far western country town where his father's family had been settled since the days of Elizabeth. Here, with no other guide than Lavoisier's "Elements of Chemistry," he set to work, and in the course of little more than a year he had made such progress, and at the same time such a reputation, as to obtain release from his indentures on his appointment as assistant to Dr. Beddoes at the new Pneumatic Institution at Bristol. In less than two years from this time we find him receiving the offer of a post at the Royal Institution in London, then newly started on its career under the influence of Count Rumford.

The story of Davy's rapid progress towards fame is in its main features familiar to the majority of educated Englishmen, but probably few persons have hitherto so completely realised, as will the readers of this book, the poetic element in Davy's character, and the large share it had in determining his choice of associates, as well as the extent to which it appears to account for the quality of some of his scientific work, and the vivacity and ardour with which he pursued his discoveries. Apparently Davy only missed being a writer of poetry in consequence of the attractions of the laboratory, and to speak of him as "poet and philosopher" is to do him no injustice. So early as 1799, soon after his arrival in Bristol, his friend Mrs. Beddoes introduced him to her sister, Maria Edgworth, and to Southey and S. T. Coleridge, with whom the acquaintance ripened into a warm friendship. Not many years later we find him in the company of Scott and Wordsworth in the lake country, and with the former, at any rate, the intimacy was sustained.

Concerning Davy's scientific work, there will perhaps always be some difference of opinion as to the relative merits of his various discoveries. Some may incline to think the isolation of the metals from the alkalis the most important; while others consider the completeness, both experimental and logical, of his inquiry into the nature of oxymuriatic acid (chlorine), which resulted in the establishment of the elemental character of this substance, entitle it to be regarded as his most perfect scientific achievement.

The invention of the safety lamp is, of course, in the popular idea Davy's greatest title to fame; but while undoubtedly the establishment of the principle of its construction represents an important service to science, it seems surprising that he should not himself have introduced some of the, rather obvious, improvements which were made soon after his time by practical men with the object of removing some of the defects of the lamp in its original form, as a protection against the dangers of the mine, and of which Davy must himself have been aware. The claim that was put forward by George Stephenson is discussed fairly in the book, and disposed of justly.

Davy was, of course, much fascinated by the "galvanic phenomena," and it is therefore remarkable that he should have said so little concerning the *arc*, which he was probably the first to observe, and of which he ultimately gave a good description. But there is no

detailed account of this wonderful phenomenon in the successive Bakerian Lectures and other papers, in which he communicated to the Royal Society the results of his numerous experiments with the battery, and only in his "Chemical Philosophy," published in 1812, is it referred to specifically. To us who live so long after, and who enjoy advantages arising directly or indirectly out of Davy's work, it seems strange that the poet, in his nature, did not supply the prophetic insight which was wanting in the philosopher.

The existence of two previous biographies of Davy—the one by Dr. Paris (1831), and the other by his brother John (1840), by no means render this new "Life" superfluous. The book has characteristics and charms of its own which ought to make it popular, and it is to be hoped that the remarkable collection of letters referred to in the preface may wholly or in part find its way into print, as the letters serve to throw an interesting light on the personality of the remarkable man by whom they were written, or to whom they were addressed, as well as on many interesting events of the time.

In reading carefully through the book two statements are to be found, which, as they are matters of fact, ought not to be matters of dispute. The author will forgive us, therefore, for drawing his attention to points in which we believe that he is misinformed.

It is true that Northmore obtained chlorine in a liquid state before this was accomplished by Davy and Faraday; but it was not by "heating the so-called hydrate of chlorine under pressure" (p. 149). Northmore used a brass condensing syringe and pear-shaped glass receivers in his experiments, and there can be no doubt that he liquefied chlorine by mechanical compression (*Nicholson's Journal*, xiii., 1806, p. 234.)

The other is a point of somewhat greater interest. On p. 126 the statement occurs that "Lavoisier never hazarded any conjecture as to the nature of potash and soda." This, however, is apparently irreconcilable with the following passage, which will be found in Lavoisier's "Collected Works," vol. i. p. 119, and which it would seem that Dr. Thorpe must have overlooked or forgotten: "L'analogie pourrait porter à croire que l'azote est un des principes constituants des alkalis en général, et on en a la preuve à l'égard de l'ammoniaque comme je vais l'exposer, mais on n'a, relativement à la potasse et à la soude que de légère présomptions, q'aucune expérience decisive n'a encore confirmées." This passage appears, of course, in Kerr's translation of the "Élémens," and a footnote is there added by the translator to the effect that, from experiments made in Germany, there is reason for supposing that soda is a modification of magnesia, and that the latter seems to be a metallic oxyd. The experiments referred to are obviously inconclusive; but, in discussing them a few pages later, Mr. Kerr makes the statement that these discoveries, if confirmed, "have been in great measure predicted by the conjecture of Mr. Lavoisier, who supposes that those substances which have long been considered as primitive earths are only metallic oxyds combined with oxygen, and that their reduction has hitherto been prevented by the attraction which subsists between them and oxygen being stronger than that between oxygen and carbon."

The translator explains in his "advertisement," at the beginning of the book, that the "new edition of the original having appeared at Paris last winter, expectations were formed that the author might have made considerable improvements; but from a correspondence with Mr. Lavoisier, the translator is enabled to say that the new edition is entirely a transcript from the former. Some very material additions, though not numerous, have been added by the translator in this edition relative to certain discoveries which have been made in some parts of chemistry since the publication of the original." From all this it appears certain that Lavoisier thought at one time that azote was a constituent of potash and soda. He may have changed his mind later, and have communicated his altered views to Mr. Kerr, but he does not seem to have put them upon record in any other way.

W. A. T.

EGYPTIAN MADE EASY.

An Egyptian Reading Book for Beginners: being a Series of Historical, Funereal, Moral, Religious and Mythological Texts printed in Hieroglyphic Characters, together with a Transliteration and a Complete Vocabulary. By E. A. Wallis Budge, Litt.D. (Cantab.), Keeper of the Egyptian and Assyrian Antiquities in the British Museum. Pp. liv + 592. (London: Kegan Paul, Trench, Trübner, and Co., 1896.)

Some Account of the Collection of Egyptian Antiquities in the possession of Lady Meux, of Theobald's Park, Waltham Cross. By E. A. Wallis Budge, Litt.D., &c. Pp. xii + 361. (London: Harrison and Sons, 1896.)

THOSE who remember the profound excitement caused by the appearance of Bunsen's "Egypt's Place in Universal History," and who now take up such a book as Dr. Budge's "Reading Book," will be surprised at the advance the study of Egyptian hieroglyphics has made since that time. Egyptology, in fact, is now on a footing of permanence which its best friends would have despaired of seeing a few years ago, and not only does it rouse the interest of the archæologist and the historian, but the student of folk-lore and of comparative religion, in his search for data, is beginning to lay under contribution its numerous legendary and mythological texts. To such a student a knowledge of the language, however slight, is of great value, as it enables him to control to some extent the translations on which he depends for information, and in many cases to understand the necessary limitations of a rendering into any modern idiom. To attain to even so slight a knowledge has been for many years extremely difficult for the beginner without the aid of a teacher, and only possible after a somewhat heavy initial expenditure in books. Last year, however, it was our duty to call attention to the publication of an extremely serviceable handbook or introduction to the study of the Egyptian language, entitled, "First Steps in Egyptian," by Dr. Wallis Budge, and it is with pleasure that we now note the appearance of a sequel to that volume in the form of a "Reading Book" by the same author, containing a series of complete texts for study. In 1888, Dr. Budge first printed these texts, and, although they appeared without

transliterations and without notes or explanations, they at least supplied the beginner with a good collection of material to work on, though he was still not in a position to walk alone. At the instance of several friends who made use of the book, Dr. Budge has now republished these compositions, breaking the lines up into words, and adding a transliteration at the foot of the page; he has also compiled a complete vocabulary to the texts, giving a number of references to each word, so that it is possible to compare their use in several passages. The student is thus enabled to acquire, without additional help, a knowledge of the language and of the principal literary compositions of ancient Egypt.

The twenty complete texts, which the volume contains, extend over a period from about B.C. 3500 to B.C. 250, and are good specimens of the various forms of composition which occur in Egyptian literature. They comprise fine examples of the biographical texts of the sixth and twelfth dynasties, of the historical inscriptions of the eighteenth and nineteenth dynasties, and of the compositions of the twenty-fourth dynasty, and of the Ptolemaic period, besides religious, moral and funereal texts of various dates. Perhaps the most attractive to the student of folk-lore, however, would be the two pieces with which the book begins—"The tale of the two brothers" and "The possessed Princess of Bekhten." Of these, the former is well known from its striking resemblance in many particulars to the tale of Joseph in Hebrew literature. The latter, however, is not so well known, and may be briefly summarised, as it throws an interesting light on the exceedingly anthropomorphic conception which the ancient Egyptian formed of his gods.

The story runs that the King of Egypt, while receiving homage in Mesopotamia from the neighbouring countries, had seen a beautiful girl, the daughter of the Prince of Bekhten, whom he married and took back with him to Egypt, giving her the title Rā-neferu. Shortly afterwards a messenger came from Bekhten with the news that Rā-neferu's younger sister was sick, and praying that a physician might come and see her. A physician was sent, but he could do no good, as he found the lady was possessed by a devil; so the Prince of Bekhten asked the king to send him a god to cure his daughter. The god Khonsu was accordingly brought with much pomp from Thebes, and arrived at Bekhten after travelling one year and five months. The demon, on beholding Khonsu, at once stated his readiness to go, but asked the god's permission that a feast should first be held to celebrate his departure. The story continues with the following quaint description of the feast of the god and the demon:—

"And the god Khonsu graciously granted this request, and spake to his priest, saying, 'Let the Prince of Bekhten make a great festival in honour of the demon.' Now, while the god Khonsu, who performeth mighty things and wonderful in Thebes, was arranging these things with the demon, the Prince of Bekhten and his army stood by in exceedingly great fear. And the Prince of Bekhten made a great festival in honour of Khonsu, who performeth mighty things and wonderful in Thebes, and they passed a happy day together; and by the command of Khonsu, who performeth mighty things and wonderful in Thebes, that demon departed in peace unto the place which he loved."

The Prince of Bekhten was so delighted that he determined to keep Khonsu in his own country, and he did so for three years, and was only induced to take him back when the god proved to him that his power had departed by appearing to him in a dream as a golden hawk, which came forth from his shrine and flew back to Egypt. This story is a good specimen of Egyptian folk-lore, and illustrates the fact that whatever abstract conceptions of a central and supreme divinity the Egyptian may have entertained, his local gods were extremely human, and endowed with very limited powers.

But if Egyptologists have not been idle in their endeavours to forward the study of the language and literature of the country, private individuals have no less been doing their share by rendering their collections of Egyptian antiquities available for students. In the years 1882 and 1885-6, Lady Meux formed a fine collection of Egyptian antiquities, containing a number of very important objects, which is perhaps, among private collections, second only to that in the possession of the Duke of Northumberland. What the late Dr. Birch did sixteen years ago for the latter collection in his "Catalogue of the Egyptian Antiquities at Alnwick Castle," Dr. Budge has now performed for Lady Meux's collection, in the work the title of which is quoted at the beginning of this review. This catalogue is privately printed, but we understand it has been distributed among scholars and the principal libraries in England and on the continent, so that the contents of the collection are now available for general study. Dr. Budge has made his catalogue as full as possible, translating and giving in full the texts which are painted or inscribed on the more important coffins, stelæ and figures in the collection; while the numerous photographic plates throughout the volume give an excellent idea of the general appearance of the larger objects. The book itself is sumptuously printed and bound, and, dealing as it does with so important a collection, will prove of the greatest value not only to the collector and the antiquary, but to all those who are interested in ethnographical studies, and who concern themselves with the history and remains of ancient religion and ritual.

THE HISTORY OF ELEMENTARY MATHEMATICS.

A History of Elementary Mathematics; with Hints on Methods of Teaching. By Florian Cajori, Ph.D. Pp. viii + 304. (New York: The Macmillan Company. London: Macmillan and Co., Ltd., 1896.)

THIS unpretentious but trustworthy book deserves a cordial welcome, and is likely to serve a very useful purpose. There is sound sense in the author's conviction that teachers of elementary mathematics may profit greatly by a knowledge of the history of the subject. They are able to arouse the interest of their pupils, in a way which would otherwise be impossible, by telling them something of the course of mathematical discovery, and of the lives of those who have made the science what it is to-day. Even a schoolboy ought to know that Euclid is the name of a man, and not that of a book; and an English lad ought surely to associate Newton with something more than the binomial theorem.

Again, the history of mathematics is of direct benefit to the teacher himself in more ways than one. The progress of scientific discovery rarely, if ever, proceeds along strictly logical lines; and of this fact mathematics affords a conspicuous example. The science took its rise from concrete problems of calculation and measurement: for a long time it remained partly empirical; and it is only in quite recent times that its axioms and postulates have been submitted to rigorous examination. The significance of this for the teacher lies in the fact that the intellectual growth of the race repeats itself to a large extent in the individual; thus in teaching the rudiments of algebra and geometry it is by far the best plan to begin with concrete problems and examples, avoiding abstract formulæ, and introducing the appropriate notation gradually, as the necessity arises.

Another wholesome result of this historical knowledge is the lesson of patience which it conveys. A teacher who is vexed and disappointed by the slowness of his class may console himself by reflecting upon the length of time which has been required by mature intellects to obtain a true conception of the nature of fractions, of negative, irrational, and complex quantities, and so on. The controversies to which these subjects gave rise, even among professed mathematicians, are very instructive in throwing light upon the psychological difficulties which every honest student of mathematics must encounter, and which the aid of a sympathetic teacher helps him to overcome.

From all these different points of view the teacher will find Prof. Cajori's book very helpful and suggestive. It is easy to read, without being superficial; it is composed with a due sense of proportion; and the limitation of its scope enables the author to enter into sufficient detail without making his work too large. Thus, for example, the account of early printed books on arithmetic and algebra is rendered extremely vivid by the insertion of numerous specimens of notation; this, more than anything else, enables the reader to appreciate not only the immense advantage of modern notation, but also the extraordinary power of men like Fermat and Tartaglia, who were able, in spite of most imperfect and inconvenient apparatus, to make discoveries of first-rate importance.

Although, perhaps, the sections devoted to the Middle Ages and the Renaissance are the most interesting and profitable, the early pages on number-systems and numerals, and on the Rhind papyrus, are likely to be the most novel to the general reader. For the mathematician it still remains to account for such resolutions as $\frac{2}{43} = \frac{1}{42} + \frac{1}{86} + \frac{1}{129} + \frac{1}{301}$, a list of which occurs in the papyrus referred to. It is difficult to see how they were obtained, or what practical purpose they were intended to serve; apparently the standard way of representing a fraction was to express it as the sum of aliquot parts with different denominators. It is not merely a question of aliquot parts. Ahnes and his contemporaries must surely have known that $\frac{2}{15} = \frac{1}{3} + \frac{1}{15}$, although even about this it may not be safe to dogmatise.

The most difficult part of a work of this kind is the discussion of modern developments. Thanks to a number of unselfish scholars, the stages of ancient and mediæval discovery have been traced out with great care and precision; and although much, no doubt, may still be done, the landmarks are familiar, and the data, after all, are limited. But a history of modern mathematics, beginning, say, with the present century, has yet to be written; and here the amount of material is so vast, and its ramifications so numerous, that to discuss it properly seems to require a trained band of specialists. In dealing with recent times, Prof. Cajori has wisely confined himself to a few points of special interest, such as the progress of trigonometry, the researches on the value and nature of π, the rise of projective geometry, and the discussion of the merits of Euclid's "Elements" as an elementary text-book. He is against the retention of Euclid, but confesses, at the same time, that in his opinion the ideal text-book has not yet appeared. He very properly protests against attempts to prove the postulate about parallels; and scores a fair hit by pointing out the inconsistency of the conservatives, who swear by Euclid and then ignore his fifth book.

The "Hints on Teaching," referred to in the title, consist of remarks suggested by the historical context, and do not form an integral part of the work. They are the observations of a practical teacher, and commend themselves by their reasonableness and common-sense. Thus, on the one hand, Prof. Cajori recommends that the concrete should precede the abstract, that proofs of the obvious should be avoided, and that in some cases logical rigour should be temporarily sacrificed; on the other, he insists on the necessity for intelligent teaching, such as will train the mind to independent thought and observation.

For the reader who wishes to pursue the subject further, there are a number of references. It may be suggested that it would be an improvement if the proportion of primary references were larger than it is. Thus, to take an example at random, on page 231 there is an account of Girard's discussion of imaginary roots of equations, and a footnote gives a reference to Cantor II. 718. This is all very well as an acknowledgment on the author's part, but the reader would prefer a reference to the page in Girard where the original passage is to be found. Secondary references of this kind involve waste of energy.

One point to which the author might well have drawn attention is the variety of projective properties of conics to be found in Apollonius. It is certain that Pascal read the "Conics"; and it is by no means unlikely that modern projective geometry springs from the study of the works of the great geometer of Perga.

A small but rather irritating matter is the inconsistency shown in the transcription of Arabic names. Why, for instance, should we have Al Battânî in two words and Albirûnî in one? And, again, why use the German transcription *dsch* when the English *j* or the international *ǧ* is ready to hand? Thus, on page 110, Abu Ća'far al-Ḥázin appears as Abû Dscha'far Alchâzin, and our old friend 'Omar Khayyám ('Omar al-Ḥajjám) masquerades as 'Omar Alchaijâmi. Let us have either a popular English approximation, or a scientific transliteration; a German popular version is simply hideous.

We may conclude with a word of praise for the biographical part of the work. So far as the limits of the book allow, the author tells us about the mathematicians

of the past what rightly interests us to know, and what the spirits of the great departed would not resent our knowing. To retail the spiteful gossip that clings to the memory of Kepler or Cardan, and to linger over the details of the Newton-Leibnitz controversy, is not the mark of a generous mind, and is utterly unprofitable besides. We are glad that, in this respect, Prof. Cajori's book is above reproach. G. B. M.

HINDU MEDICINE.

A Short History of Aryan Medical Science. By H. H. Sir Bhagvat Sinh Jee, K.C.I.E., M.D., D.C.L., L.L.D., F.R.C.P.E., Thakore Saheb of Gondal. Pp. 280; with 10 plates. (London: Macmillan and Co., Ltd.)

THE author, an Indian prince, after studying medicine with diligence and distinction in this country, applied himself on his return to India to a study of the ancient medical science of Hindustan. As a result, he presents in this treatise a bird's-eye view of the marvellous civilisation of India, and he does so from the point of view of a Hindu, in a spirit of faith and optimism creditable to his piety and patriotism. Perhaps a larger exercise of the critical faculty might have been more acceptable to Western intelligence, especially as, in some matters of history and chronology, the author is at issue with European authorities; but it might also have spoiled the picture, which is simple and bright. The writer prefaces his account of Indian medical science by a brief sketch of the early civilisation of the Hindus and of their religion, philosophy, science and art. The science and art of medicine were an important feature in this great system, elaborated according to the same principles and by the same methods as other branches of knowledge, and therefore possessing the same merits and the same faults. "The Hindus believe," the author tells us, "that like all their other sciences, the science of medicine has been revealed to them."

The bible of medicine is the "Ayur Veda," whose authorship is attributed to no less a personage than Brahma. Subsequent commentators, chief among them Charaka and Sushruta, have reproduced and somewhat amplified this record. The author, with great insight and judgment, gives an interesting history and epitome of the doctrines and practices laid down in these works, of which he appends a list of 107. We observe that he has not included among these the "Navanitaka," an ancient Sanskrit medical manuscript found by Captain Bower at Kuchar, in Eastern Turkestan, in 1890, and which is believed to be older than the works of Charaka and Sushruta. The development of science by the wise men of the East was a mixture of observation and contemplation. Their observation was keen though somewhat crude, but when the results were submitted to the process of intellectual digestion, an excessive addiction to analysing and systematising produced a code of knowledge into which imagination largely entered, and which was specious and unsound. The product, possessing the character and sanction of a revelation, became straightway a fixed guide, which has remained authoritative and unaltered through the ages. The early medical observers scrutinised closely the structure and functions of the human body, and not content with noting and recording these, they must fully and finally explain them. For this purpose they invented three principles or essences or spirits—*vata*, *pitta*, and *kafa*—wind, bile, and phlegm, which, acting upon and through the constituent parts of the body, gave rise to all the manifold physiological manifestations of the organism. Disease was held to arise from excess, defect, or disorder of one or more of these humours, and the object of the physician in examining the patient, was to detect which humour or humours were at fault, and select the remedy calculated to restrain, stimulate, or correct the aberrant fluid. A doctrine of temperaments was built on the same basis. Associated with these hypothetical spirits, other supernatural agencies were postulated; faults committed in a former state of existence, and the operations of demons, were included among disease causes. It is not surprising, therefore, that rites, ceremonies, amulets, omens, and charms entered largely into treatment. The Thakore Saheb advances strong claims for the antiquity and excellence of Indian medicine. He contends that the medical science of the Greeks, Egyptians, and Arabians, was extensively borrowed from India. He asserts that Jenner and Pasteur were anticipated in the matter of protective inoculation, Morton and Simpson in anæsthesia, Lænnec in auscultation, Piorry in percussion, and Lister in antiseptics by Indian sages; that the vaunted discovery of Harvey was also presaged, if not preceded, by Indian doctrines regarding the circulation of the blood. He shows that modern medicine has derived important practices, such as massage, and many useful drugs, from India, and even goes the length, in apologising for the shortcomings of Indian surgery, of asserting that in ancient times the use of drugs prevented or dispersed tumours, and other conditions now demanding surgical intervention. He expounds at some length the rules of hygiene and disease prevention laid down by the *rishis*. They are mostly personal, and their elaboration is astonishing. Life to the orthodox Hindu was a series of minute rites governing every item of daily existence—some salutary, but most of them frivolous.

Still, with all its absurdities, Indian medicine was a triumph of acumen and industry, and the author has succeeded in placing a very clear and complete compendium of it on record in this book, which he who runs may read. Perhaps his hope that rational and progressive medical science may still be able to learn something from Aryan medical science is a feasible one; but the materials and methods of the latter must to that end be recast in the furnace of modern inductive research.

OUR BOOK SHELF.

On the Adjustment and Testing of Telescopic Objectives. By T. Cooke and Sons. Second edition. Pp. 96. (York: Delittle and Sons, 1896.)

THE first edition of this admirable little volume appeared in the year 1891, and since that time its fame has spread abroad, and both German and Italian translations have been made. In this short interval of time a very notable advance has been made in the construction

of objectives. The new triple photo-visual objective is the outcome of experiments made by Messrs. Cooke's optical manager, Mr. H. Dennis Taylor, in the direction of improving the so-called achromatic telescope. The success with which he has been rewarded, has given astronomers an objective which is not only free from colour aberrations, but which can be used for celestial photography without the necessity of any further adjustment.

In the present edition this new lens is fully referred to, and the communications of Mr. Dennis Taylor to the Royal Astronomical Society are reprinted in full. A supplementary chapter is also added, describing the adjustments of its component parts; this will, no doubt, prove most serviceable to those who are the fortunate possessors of this lens.

In the main, the general text of the book has not been very considerably disturbed; modified views, and the insertion of up-to-date information, have of course required here and there changes in the text, and to some extent enlargement.

Users of telescopes cannot do better than make themselves thoroughly acquainted with the contents of this excellent and valuable source of information. It must be remembered that we are here enabled to make use of the knowledge of those well experienced in the making and testing of numerous objectives, and amateurs and others may gather many a wrinkle, the knowledge and use of which will make all the difference between the bad and good working of an objective with which they are making observations. W. J. S. L.

Fuel and Refractory Materials. By A. Humboldt Sexton. (London: Blackie and Son, 1896.)

THIS book is intended to meet the want of a manual intermediate in size between the exhaustive treatises of Percy, Mills, and Rowan on the one hand, and such brief outlines of the subject as may be found in manuals of metallurgy on the other. Seven chapters out of fifteen are devoted to fuel, one to the recovery of bye-products, three to furnaces and refractory materials, whilst the subjects of pyrometry, calorimetry, utilisation and testing of fuel are dismissed in one chapter each. The book is written in a clear and concise style, and is profusely illustrated with excellent diagrams. The subjects of coking, recovery of bye-products, and preparation and use of gaseous fuel are treated in a very practical manner and in great detail. The chapter on the important subject of pyrometry is not so satisfactory, as although an account is given of almost every type of instrument, whether obsolete or not, the impression is given that the author has little practical knowledge of many of the instruments described, as scarcely any criticism is offered, and the descriptions are often in the inventor's own words. The result is that an engineer, wishing to put in a pyrometer for practical purposes, would receive little assistance in choosing the best type of instrument for any special case. An exact definition of the various thermometric "scales" of the several instruments would also be desirable, so that the exact meaning of a temperature measured, say on the platinum resistance scale, could be clearly shown. The same historic completeness and lack of criticism applies to the chapter on calorimetry; a student might get the idea that for practical purposes it is a matter of indifference whether the heat of combustion of a fuel be determined by Berthier's process (fusion with litharge) or by the Berthelot-Mahler process. Taking the size of the book into consideration, very few essential points have been omitted. It is to be hoped, however, that in the second edition space may be found in Chapter x. for a description of an anemometer of the Fletcher type, the direct measurement of the gaseous velocity in a shaft being much preferable to the indirect methods given. The approximate analysis of flue gases is now so common in works, that a short account of the methods used, together with an application (such as a boiler trial), would be very useful. The only method mentioned for carrying out such analyses is both cumbersome and expensive. At the end of the book is an admirable set of references to works and papers bearing on the subject.

The Lepidoptera of the British Islands; a Descriptive Account of the Families, Genera and Species indigenous to Great Britain and Ireland, their Preparatory States, Habits and Localities. By Charles G. Barrett, F.E.S. Volume III. HETEROCERA: *Bombyces*, *Noctuæ*. Pp. 396. 8vo. (London: L. Reeve and Co., 1896.)

THE present instalment of Mr. Barrett's voluminous work includes the following families: BOMBYCES: *Bombycidæ* [more correctly *Lasiocampidæ*], *Endromidæ*, *Saturnidæ*, *Drepanulidæ*, *Notodontidæ*. NOCTUINA: *Cymatophoridæ*, *Trifidæ* (*Diphthera* to *Agrotis*).

The habits, localities and transformations of the various species are dealt with at considerable length, and practically include most of the available information respecting British *Lepidoptera* likely to be useful to a practical collector. Information respecting the occurrence of British species abroad is likewise furnished in most instances, and reputed British species are also mentioned incidentally.

Entomologists who do not confine their studies to British insects, and who are more interested in classification than in habits, will find Mr. Barrett's remarks on the structure, pattern and classification of that extensive group of moths (the *Noctuæ*) well worth perusal. They form one of the most dominant groups of the larger moths at the present day; but they are very compact, and it is exceedingly difficult to find satisfactory characters by which they can be divided into families. This has been attempted by Guenée, but many writers since his time have abandoned the idea of subdividing the *Noctuæ*, except into genera. Mr. Barrett evidently recognises three main families at least; but we shall be interested to see where he places some of the more aberrant genera usually included in the *Noctuæ*, when he arrives at them in later volumes of his work.

How to Study Wild Flowers. By the Rev. George Henslow, M.A., F.L.S., F.G.S., &c. Pp. 224 (with fifty-seven illustrations). (London: The Religious Tract Society, 1896.)

THIS is a useful little book, and doubtless it will be welcome to many people who live in the country, and who may desire to gain a systematic acquaintance with the flowering plants around them.

We could wish, however, that the author had emphasised the "Floral Formula" part of the business a trifle less, and had given a little more attention to floral diagrams instead. As regards the latter, we might remark that the position of the mother-axis ought always (if possible) to be indicated in the diagrams, otherwise how are his readers to tell which aspect of the flower is posterior and which anterior? A neglect of this necessary adjunct to these figures will tend to render such diagrams as the learner may attempt to construct for himself quite useless, inasmuch as his attention is not directed, as it ought to be, to a definite orientation of the different parts of the flower.

Some of the plants receive a somewhat desultory treatment; but notwithstanding this, and in spite of some errors we have noticed, the book is well worth looking into, on account of the refreshing number of interesting first-hand details which it contains.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On a New Law Connecting the Periods of Molecular Vibrations.

IN the current number of NATURE you were good enough to print a short article by me, announcing a discovery which I believed was new. My attention has now been drawn to the fact that it was published a few months ago by Rydberg (*Wied. Ann.*, vol. lviii. p. 674), to whom the honour of the discovery therefore belongs. My excuse for being unacquainted with Rydberg's paper must be found in a prolonged absence from home last summer, and the large amount of unread scientific literature which I consequently found on my return home. There is, moreover, nothing in the title of Rydberg's paper which would indicate the important nature of its contents. If by writing to you on the subject I have drawn the attention of physicists to what I consider the most important fact yet brought to light concerning molecular vibrations, my article will have served some good purpose. ARTHUR SCHUSTER.

The Athenæum, Pall Mall, S.W., January 2.

The Pound as a Force.

A VERY few words are necessary from me in answer to Prof. Perry's letter on page 177. First and foremost (though referring to the latter part of his letter, not to the cow and bridge portion), if any sentence in my previous communication can have led any one to imagine that I consider Prof. Perry anything but a most admirable teacher of his own subject, that sentence must have been villainously expressed. Secondly, when I said that engineers had mostly to deal in their calculations with bodies either at rest or in uniform motion, I thought I was speaking in the sense of Prof. Perry's original article (he said the same thing himself near the top of column 1, page 50), and that I should have his concurrence: I would not for a moment argue such a point with him. If I had thought it necessary to be cautious I would have used the word "suggest" instead of the word "tell" in my sentence about acceleration: to the idea in which however I still respectfully adhere. And in general I adhere to all the *matter* of my last communication, though with full deference to his criticism on the *manner* of it. Thirdly, I cannot remember that I have ever specially "advocated" the poundal. I have never much liked it, but it is useful as a stepping-stone to higher things, in a way that the familiar pound-weight is not. Fourthly, I agree with Fitzgerald that Newton's second law furnishes by no means the only measure for quantity of matter (chemical equivalence also furnishes a measure), but inertia is the fundamental property and measure for dynamical purposes. Fifthly, we do not "assume" that inertia is proportional to weight; we verify it within certain limits of error by dropping bodies (like Galileo), or (like Newton) within narrower limits by swinging pendulums: essentially the same process. Sixthly, I do not, alas, find it at all easy to give full marks to a student for his answer to such a question as "What is Ohm's law?"; and, although I cannot plead guilty to the accusation of having spoke disrespectfully either of Gravity or of Engineers, I do find that occasionally the treatment of the former by the latter leaves something to be desired in point of clearness; the occasional educational remarks of the periodical called *The Engineer*, for instance, seem fairly representative of a large and influential class. And lastly, although a remark immediately following his citation of a familiar electrical equation leads me to think that Prof. Perry still misses the chief point of my letter, yet there are quantities of things in the present correspondence on which we agree; and chief among them is the profound conviction we share that there is a crying need for reform in our whole system of secondary education. OLIVER J. LODGE.

Liverpool, December 27, 1896.

The Theory of Dissociation into Ions.

THE numerical agreement obtained when certain properties of solutions are interpreted on the theories of osmotic pressure and ionic dissociation is undoubtedly very striking, and it is, consequently, not very surprising that these theories have obtained such a ready acceptance. Whatever may be our opinions as to the validity of the theories, and even of the harm which has been done by pressing them too far, we cannot but recognise that they have been the origin of much good work on a condition of matter which is, at the same time, one of the most obscure and one of the most important, both from the physicist's and chemist's point of view. But, however convenient such theories may be as working hypotheses, their advocates should not have forgotten that they depend solely on the numerical relations alluded to, and that something more than this is required before such hypotheses can be raised to the level of acceptable theories, and far more before they should be held up as an indispensable article of faith, which unless a chemist believe he cannot be saved.

For a theory to be acceptable it should, at the very least, be reasonably probable, and should not violate any fundamental and well-established facts; it should stand the test of any apparently crucial experiments brought forward to settle between it and its rivals, and, I think we may add, it should give some explanation, not simply of the behaviour of matter in the condition in question, but also of why matter ever assumes such a condition.

The theories of osmotic pressure and ionic dissociation, I believe, have not done this. Even if we can accept as probable the view that atoms united so firmly together, as we have every reason to believe are those of, say, chlorine and hydrogen, will fly affrighted from each other at the mere approach of a few water molecules, which are represented as being more or less inert and destitute of any strong attraction for the dissociated atoms; even if we can imagine that these atoms, so strongly charged with electricity of opposite signs, can meander about in the liquid, with a supreme disdain for their former associates and the attractive charges which they carry; even if we can reconcile this indifference with the behaviour of these very atoms to a similar electric charge on other similar companionable atoms, when these latter happen to be agglomerated into the form of an electrode; even if we find no difficulties in all this, still we must admit that the theories in question afford no explanation whatever why a substance should dissolve at all, and they can, therefore, hardly be accepted as a sufficient explanation of solutions. We cannot treat Nernst's statement that a substance goes into solution because it has a "solution pressure" seriously, and, in cases where the dissolved substance is known to form hydrates, the view that an excess of water will decompose these hydrates, and free the substance entirely from its union with water, without the formation of any other compounds, is quite opposed to our knowledge of the action of mass in chemical changes.

Nor can we ignore the thermal difficulties in which the theory of dissociation lands us; for if, to satisfy the facts of the case, we admit that dissociation is accompanied by a large evolution of heat, we must suppose, either, that the evolution which accompanies the reverse action when the water is absent (*e.g.* $H_2 + Cl_2 = 2HCl$, gases), is due to heat being evolved by the dissociation of molecules of elements into their atoms, or, as has been asserted, that the atoms of the dissolving electrolyte evolve heat by combining with their electric charges, a novel method of evolving heat, which should long ago have made the fortunes of the discoverers, especially as the charges with which the atoms combine come into existence of their own accord, and without the expenditure of any external energy.

Turning to the "crucial" experiments suggested, we do not find the results to be any more satisfactory from the point of view of the theory. We have on the one side two experiments heralded in by Prof. Ostwald with great flourish of trumpets; the "imaginary" experiment already quoted by Dr. Herroun, in which an ultra-microscopical trace of liquid is electrolysed by an electrostatic discharge, and the "arm-chair" experiment of "chemical action at a distance," the results of both of which might have been predicted, as I have shown elsewhere, by any one possessing an elementary knowledge of electricity, long before the dissociation theory was dreamt of.

On the other side we have two experiments, which would seem to be conclusive, but which the dissociationists have hitherto thought fit to ignore.

Osmotic pressure, they hold, is due to the quasi-gaseous pressure of the solvent and dissolved substance acting on a diaphragm, which, being permeable to the solvent only, renders the pressure of the dissolved substance inoperative, and hence

causes the total operative pressure of the solution to be that of only the solvent present in it. Now, I have shown that if we take a solution such as that of propyl alcohol in water, and place it in a semipermeable vessel surrounded by water, the latter will pass through towards the solution, *ergo*, the vessel is permeable to water but impermeable to the alcohol; but if the same vessel with its same contents is surrounded by propyl alcohol, it is the alcohol that passes through towards the solution, *ergo*, the vessel is permeable to the alcohol, but not to the water, and must, therefore, at the same time, be both permeable and impermeable to each substance; which is absurd. The obvious conclusion to draw from this experiment is, that it is the solution, and not either of the substances separately, to which the membrane is impermeable, and this is just what we should anticipate on the hydrate theory, the molecules of hydrates being necessarily larger than those of their constituents.

As to ionic dissociation: When one molecule of sulphuric acid is added to 100 molecules of water, if no change occurs, we shall have a total of 101 molecules, entities or acting units, whatever they may be called; if hydrates are formed, we shall have less than 101 acting units; and if dissociation occurs, we shall have more than 101. Relying on the depression of the freezing-point, the dissociationists maintain that this last is the case, and that something between 101 and 103 acting units are present; but, if this method is really to be trusted, it proves too much, for by measuring the depression of the freezing-point of a large bulk of acetic acid produced by adding to it bodily the $100H_2O + H_2SO_4$, we find that this mixture contains very considerably less than 100 acting units, instead of more.

The explicit evidence afforded by such experiments surely calls for some comment on the part of those whose theories seem to be negatived by it, and their silence on the subject is so significant that it is surprising that it should not have attracted more attention than it has.

The strong evidence of the existence of compounds such as hydrates in solutions, both concentrated and weak, is inconsistent with that perfect freedom of molecules and atoms postulated by the dissociationists, but the discussion of this evidence cannot be attempted here.

The hydrate theory did not lead, and probably never would have led to an explanation of that peculiar behaviour of electrolytes which simulates dissociation, but, as I showed some years ago (*Ber. deutsch. chem. Gesell.*, and, in outline, in an article on Solutions in "Watts' Chemical Dictionary"), the theory is perfectly consistent with the observed facts, and, further, affords an explanation of them, which is free from the serious objections attaching to the dissociation theory.

Bath, December 23, 1896. SPENCER PICKERING.

Some Neural Descriptive Terms.

IN a recent circular asking the opinion of experts as to the prevailing and preferred usage of anatomic and neurologic terms, on behalf of the projected Dictionary of Philosophy and Psychology, Dr. C. L. Herrick mentions certain terms and principles which have been either proposed or adopted by me.

But for the request to "respond as early as possible," I should suggest that replies be either delayed or regarded as provisional until after the appearance of my paper, "Neural Terms, International and National" (*Journal of Comparative Neurology*, vi. pp. 216–340, December 1896), wherein the general subject is discussed at length, and in parallel columns are given the neuronyms adopted by the Anatomische Gesellschaft in 1895, and those now preferred by me. But for the remoteness of Dr. Herrick's present address the following comments would be submitted to him first.

3 (*b*). For the part now called by the Gesellschaft "Substantia perforata lateralis," I formerly proposed *præperforata*, but since 1889 have employed *præcribrum*.

4 (*e*). *Metencephalon*, as employed in the last three editions of "Quain," and adopted by me in 1881, designates the last definitive encephalic segment, *i.e.* between the cerebellar segment (our epencephalon) and the myelon or spinal cord. As given in the circular, it has two other usages, viz. either for the cerebellar segment alone (His), or for both regions (some authors). The encephalic segments will form the subject of a paper at the coming meeting of the Association of American Anatomists.

(*g*). *Metencæle* is doubtless a misprint for *metacæle*. The Latin (international) forms are *metacælia* and *mesocælia*; the national English forms *metacele* and *mesocele*.

(*j*). As to *Neuron* (proposed by me in 1884 as a mononym for *axis cerebro-spinalis*) see "Reference Handbook," ix. 100, and *Proceedings Assoc. Amer. Anat.*, 1895, 44–45. Indirect endorsement of it is contained in such compounds as *neuromere*, *neurenteric*, &c. In like manner *myelencephalon* (for either the entire cerebro-spinal axis or for the last encephalic segment) embodies indirect endorsement of *myelon* for *medulla spinalis*.

As to *cephalic* and *caudal*, *cephalad* and *caudad*, during an experience of sixteen years no actual instance of misapprehension has been observed. But since they evidently are not acceptable to some, might not the increasing employment of *præ* and *post* in composition with the force of adjectives justify taking these prepositions as the bases of adjectives, viz. *præalis*, *postalis*; Eng., *præal* and *postal*; adverbs, *præad* and *postad*? As mere vocables the last two are no more objectionable than *quoad*.

Classic precedents for the derivation of adjectives from prepositions or adverbs are *contrarius*, *extraneus*, *proprius*, *crastinus*, *pristinus*, *interior*, *supernus*, and ἀνώτερος.

Ithaca, N.Y., December 19, 1896. BURT G. WILDER.

Measurement of Crabs.

IN his letter of December 3, Mr. Cunningham suggests that if the young crabs be compared so that the frontal ratio is taken as the standard of comparison between the respective groups of the two years, the difference will be one of carapace length only, and this may be due to variation in the food supply. But he does not explain why the effect of the supposed variation in the food supply should be confined to the one dimension of carapace length, and not extend to the frontal ratio also. There is no evidence to lead us to suppose that the change of frontal ratio is a more accurate criterion of development than carapace length; but whichever be taken as a basis for comparison, the result is a change of shape in the carapace as between the two years.

I have, however, to make a correction as to the *adults*, two groups of which, belonging to different years, I compared in my paper as being equal and comparable. I had reason for thinking that they were equal; but I regret to say that a more accurate investigation of them, to which I was led by Mr. Cunningham's criticisms, shows me that they were not so, and that the inequality was not a natural one, but was due to an unconscious selection in the process of collecting them; and therefore these two groups are not comparable, and must be eliminated from a consideration of the question.

December 28, 1896. H. THOMPSON.

Marriage of the Dead.

MARCO POLO narrates of the Tartar tribes thus:—"They have another notable custom, which is this. If any man have a daughter who dies before marriage, and another man have had a son also die before marriage, the parents of the two arrange a grand wedding between the dead lad and lass. And marry them they do, making a regular contract! And when the contract papers are made out they put them in the fire in order that the parties in the other world may know the fact, and so look on each other as man and wife. And the parents thenceforward consider themselves sib to each other just as if their children had lived and married. Whatever may be agreed on between the parties as dowry, those who have to pay it cause to be painted on pieces of paper, and then put these in the fire, saying that in that way the dead person will get all the real articles in the other world" (Yule, "Book of Ser Marco Polo," 2nd ed., vol. i. pp. 259–260). On this narration of Polo, the late Colonel Yule, quoting the authors of later date, remarks that "this is a Chinese custom, though no doubt we may trust Marco for its being a Tartar one also" (p. 260).

As it is not well known whether or not there is a record of this strange custom earlier than the beginning of the dynasty of Yuen, I was in doubt whether it was originally common to the Chinese and Tartars until I lately came across the following passage in "Tsoh-mung-luh" (Brit. Mus. copy, 15297, *a* 1, fol. 11–12), which would seem to decide the question—"In the North there is this custom. When a youth and a girl of marriageable ages die before marriage, their families appoint a match-maker to negotiate their nuptials, whom they call 'Kwei-mei' (*i.e.* 'Match-maker of Ghosts'). Either family hands

over to another a paper noticing all pre-requisites concerning the affair; and by names of the parents of the intended couple asks a man to pray and divine; and if the presage tells that the union is a lucky one, clothes and ornaments are made for the deceased pair. Now the match-maker goes to the burying-ground of the bridegroom and, offering wine and fruits, requests the pair to marry. There two seats are prepared on adjoining positions, either of which having behind it a small banner more than a foot long. Before the ceremony is consecrated by libation, the two banners remain hanging perpendicularly and still; but when the libation is sprinkled and the deceased couple are requested to marry, the banners commence to gradually approach till they touch one another, which shows that they are both glad of the wedlock. However, when one of them dislikes another, it would happen that the banner representing the unwilling party does not move to approach the other banner. In case the couple should die too young to understand the matter, a dead man is appointed as a tutor to the male defunct, and some effigies are made to serve as the instructress and maids to the female defunct.[1] The dead tutor thus nominated is informed of his appointment by a paper offered to him, on which are inscribed his name and age. After the consummation of the marriage the new consorts appear in dreams to their respective parents-in-law. Should this custom be discarded, the unhappy defuncts might do mischief to their negligent relatives. . . . On every occasion of these nuptials both families give some presents to the match-maker ('Kwei-mei'), whose sole business is annually to inspect the newly-deceased couples around his village, and to arrange their weddings to earn his livelihood."

This passage is very interesting, for, besides giving us a faithful account of the particulars, which nowadays we fail to find elsewhere, it bears testimony to the Tartar, and not Chinese, origin of this practice. The author, Kang Yu-chi, describes himself to have visited his old home in Northern China shortly after its subjugation by the Kin Tartars in 1126 A.D.; so there is no doubt that among many institutional novelties then introduced to China by the northern invaders, Marriage of the Dead was so striking that the author did not hesitate to describe it for the first time.

According to a Persian writer, after whom Pétis de Lacroix writes, this custom was adopted by Jenghiz Kân as a means to preserve amity amongst his subjects, it forming the subject of Article XIX. of his Yasa promulgated in 1205 A.D. The same writer adds:—"This custom is still in use amongst the Tartars at this day, but superstition has added more circumstances to it: they throw the contract of marriage into the fire after having drawn some figures on it to represent the persons pretended to be so marry'd, and some forms of beasts; and are persuaded that all this is carried by the smoke to their children, who thereupon marry in the other world" (Pétis de Lacroix, "History of Genghizcan the Great," trans. P. Aubin, London, 1722, p. 86). As the Chinese author does not speak of the burning of papers in this connection, whereas the Persian writer speaks definitely of its having been added later, it seems that the marriage of the dead had been originally a Tartar custom, with which the well-known Chinese paper-burning was amalgamated subsequently between the reigns of Genghiz and his grandson Kublai—under the latter Marco witnessed the customs already mingled, still, perhaps, mainly prevailing amongst the Tartar descendants. KUMAGUSU MINAKATA.

The Heating of Anodes in X-Ray Tubes.

IN reply to Mr. Walter Chamberlain's inquiry (p. 198), it must be borne in mind that spark length is not *per se* a criterion of the energy delivered to a vacuum tube. The length of spark is more or less proportionate to the maximum E.M.F. of the discharge, while the energy of a discharge depends upon the nature of the curves of both E.M.F. and current, and may bear but a small relation to the maximum E.M.F. Large coils which have secondary wire of considerable section and comparatively large electrostatic capacity, give a much greater electric quantity and, consequently, much more energy for each discharge, even when worked so as to give only short sparks, than do smaller coils the secondary wire of which is of smaller section and capacity.

Röntgen-ray tubes should be excited during exhaustion with a coil of the same dimensions as the one that they are ultimately destined to be worked with. This is a point which does not seem to receive sufficient attention from commercial tube manufacturers. A. A. C. SWINTON.

66 Victoria Street, London, S.W., January 1.

Sesamoid Bones.

JUDGING from a small collection of X-ray photographs made during the year, the female hand seems better provided with sesamoid bones than the male.

In my prints, in the female hand a sesamoid is most often found in the metacarpo-phalangeal joint of the little finger, less frequently in the index: in one case there are two in the inter-phalangeal joint of the thumb; in this hand, including the two always found in the metacarpo-phalangeal joint of the thumb, there are no less than six sesamoids. In male hands the bones seem to be more evenly divided between the index and fifth fingers. In most cases the sesamoids are larger in the female hand. F. J. REID.

December 26, 1896.

Discharge of Electricity by Phosphorus.

THE discharging power for electricity of slowly oxidising phosphorus appears to have been known for much longer than Messrs. Elster and Geitel (see p. 155) seem to be aware of.

In the 1855 edition of the "Encyclopædia Britannica," vol. viii. p. 622, an apparatus is described for collecting atmospheric electricity, first used by Matteucci, in which a piece of phosphorus projecting from a glass tube is connected to an electrometer by a long wire, and exposed to the air whose electrical state is to be investigated. It is said to have been found very useful for this purpose. J. R. ASHWORTH.

Rochdale, December 26, 1896.

Shooting-stars observed on January 2.

THIS morning, between six and seven o'clock, there has been a very unusual number of shooting-stars. The radiant point was somewhere near Corona. I saw, on the whole, two or three dozen. The brightest was not much inferior to Jupiter.

Sheffield, January 2. H. C. SORBY.

THE GEODETIC SURVEY OF SOUTH AFRICA.[1]

THE Report on the Geodetic Survey of South Africa, presented to both Houses of the Cape Parliament, and printed in Blue-book form, is interesting and important. It is a record of geodetic work well planned and ably carried out, and it has a permanent value, not only from a scientific point of view, but as an accurate basis upon which all future surveys of the country may be confidently founded.

Soon after his appointment as H.M.'s Astronomer at the Cape in 1879, Dr. Gill recommended that a geodetic survey should be commenced, and formulated a scheme "for a gridiron system of chains of principal triangulation extending over the Cape Colony, the Orange Free State, Natal, and the Transvaal." His recommendations were cordially supported by Sir Bartle Frere and Sir George Colley, then respectively Governors of the Cape Colony and Natal; but it was not until June 1883 that the work was fairly commenced, by the measurement of a base-line in Natal. On the completion of this operation, severe pressure was applied by the Government of Natal to accelerate the work at the expense of accuracy; and on two subsequent occasions the question of suspending the survey was seriously considered. It was no easy task to convince Governors and Ministers that true economy lay in "basing all future surveys upon a principal triangulation of such accuracy, that its results might be

[1] The last clause in original text is doubtful in reading. Perhaps it will be more correct to render it: "And the family of the intended bride provides her with various sorts of utensils and apparel needful to her nurse and maid-servants in the other world."

[1] "Report on the Geodetic Survey of South Africa." Executed by Lieut.-Colonel Morris, R.E., C.M.G., under the direction of David Gill, H.M.'s Astronomer at the Cape. Parliamentary Paper. Pp. xii + 291. (Cape Town: Richards, 1896.)

considered definitive for all future time"; but Dr. Gill succeeded. By a happy combination of tact and firmness he was able to resist all attempts to lower the standard of survey, and, in the face of grudging support, to carry out a considerable portion of his original scheme. Maclear's arc has still to be extended to Port Nolloth, and this extension to be connected with Mr. Bosman's excellent triangulation in Bechuanaland; the eastern end of the latter triangulation has to be connected with the geodetic triangles near Kimberley, and Kimberley, through the Orange Free State, with the Natal triangulation. When these operations have been completed, let us hope in a not far distant future, they will yield an arc of 14° of longitude.

Dr. Gill's success thus far leads him to look forward and ask whether the progress made in geodetic survey in South Africa might not be regarded as the first step in a chain of triangulation which shall extend continuously to the mouth of the Nile. Further he would, by an additional chain of triangles along the coast of the Levant, and through the islands of Greece, connect the African and Greek triangulations, and so, with Struve's great arc of meridian, measure an arc of meridian 105° in amplitude. Even though the completion of a work of such magnitude cannot be expected for many years to come, Dr. Gill has done good service by pointing out the mode of procedure that might be adopted, and the desirability of at once undertaking the definite survey of Egypt. Proposals for such a survey were made soon after the British occupation, but, for financial reasons, which would probably be still urged, they were not entertained. We trust, however, that the commencement of a work of such economic value to Egypt, and of such geodetic importance, will not be much longer delayed.

Dr. Gill was most fortunate in the officer selected to take charge of the field operations. Captain (now Lieut.-Colonel) Morris, R.E., C.M.G., made, personally, nearly the whole of the astronomical observations, and of the measurements of the angles of the triangulation, as well as the greater part of the computations. He also arranged for the transport of the delicate instruments over much rough country, managed distant heliostat parties, looked after men, horses and cattle, and, with much tact, persuaded the farmers to allow beacons and observatories to be erected on their lands. When it is remembered that the 18-inch theodolite with its stand weighed 1042 lbs., and that it was packed in five boxes, of which that containing the body of the instrument weighed 400 lbs., the transport difficulties are apparent. The able manner in which Colonel Morris carried out his duties may be gathered from his Report, which fills a large portion of the Blue-book, and the fact that no breakdown occurred at any time throughout the work. As Dr. Gill well says: "Colonel Morris' services have been such as very few men have the combined physique and capacity to render."

The survey was carried out with great care and accuracy with the improved instruments of the present day, and it takes a high place amongst the geodetic surveys of the world. The standard of measure was the Cape 10-foot standard Bar A., the length of which, in terms of the international mètre, was determined at Breteuil by M. Benoit, then Chief Assistant of the International Bureau of Weights and Measures. The constants of two Tonnelot thermometers, for employment in the comparison of the base-apparatus with the standard, were also investigated at Breteuil under the direction of Dr. Brock. The base-measuring apparatus, made by Troughton and Simms, consisted of five 10-foot steel bars, "so mounted as to be conveniently handled and aligned, and provided with means for determining the instantaneous temperature of each bar." The steel bars were compared with the standard by means of an instrument, the Comparateur, designed by Dr. Gill, of which a full description, with plates, is given.

Three base-lines were measured, each by a different method. The Natal base was measured throughout its whole length, 10,800·45 feet. The line was divided into three sections of about 3600 feet, and each section was measured backwards and forwards in successive horizontal 50-foot lengths. The verification of the base showed a close agreement (a difference of ·0002 feet in the one case, and of ·0027 feet in the other) between the two outer sections as derived, respectively, by direct measurement, and by triangulation from the central section. As this appeared to show that accuracy could be obtained without the measurement of long base-lines, it was decided in the case of the Port Elizabeth base to measure only about 5600 feet, and afterwards to prolong it both ways to a total length of 17,058·49 feet. The measured base was divided into eight sections of 700 feet, each of which was measured forward in ascending, and backward in descending temperatures, and the measurements were, as far as possible, completed the same day. In the Kimberley base 6000 feet were measured, and the prolongation to 14,760·3 feet was all in one direction. Here the measured base was divided into twelve sections, so as to ensure the completion of the forward and backward measurements in the same day. The probable errors in the lengths of the three bases are: Natal ± 0·140 inches; Port Elizabeth ± 0·072 inches; Kimberley ± 0·081 inches. The probable error of the Zwaartland base, measured by Maclear with the Colby compensating apparatus used for the measurement of the Lough Foyle base, is ± 2·362 inches.

For the triangulation two instruments were used: an 18-inch theodolite by Troughton and Simms, and a 10-inch theodolite by Repsold of Hamburg. The larger theodolite, though an admirable instrument, was inconvenient from its great weight and bulk; and, in spite of every care, the pivots, being made of comparatively soft material, became slightly deformed by wear. The Repsold theodolite was much more portable than the 18-inch, being less than a quarter its weight; it had hardened steel pivots which stood seven years' hard service, and it could be used both as a transit instrument and as a zenith telescope. It was consequently exclusively used, after its introduction, for astronomical observations, and the measurement of horizontal angles; and it seems to be an excellent instrument for geodetic work in a country where difficulties of transport may be expected. The probable error of an observed angle with the 18-inch is ± 0″·49, and with the 10-inch ± 0″·33. These results, especially the latter, compare well with those of the best geodetic surveys of other countries. Those obtained with the Repsold are only inferior to the results of the survey of Saxony (± 0″·23), and of the U.S. Coast Survey—San Francisco and Salt Lake series (± 0″·25). The interesting table of probable errors of measurement of a single angle in the best surveys given by Dr. Gill, shows how far the Ordnance Survey (probable error ± 1″·19) has been left behind by more recent surveys, and how desirable it is, from a scientific point of view and in the interests of geodesy, that the angles of the principal triangulation should be remeasured with the more perfect instruments of the present day.

The measured bases of the South African survey were connected by chains of triangles; and other stations, including those of Maclear's survey, were adjusted to the system of the geodetic circuit. A good account of the circuit solution is given by Colonel Morris in his Report. The observations of vertical angles were generally taken in the afternoon, when the effects of vertical refraction were most uniform, and the heights were adjusted on the same principle as the horizontal angles. The results were satisfactory. The difference between the levelled height of Zwaartkop Mountain

station, and the height, determined by computation, through a chain of triangles over 400 miles long, from Buffelsfontein station, the height of which was determined by levelling operations at Port Elizabeth, was only 1·6 feet.

Most of the astronomical observations were made with the Repsold theodolite, but before its arrival the latitudes were determined by a Talcott zenith telescope, constructed by Troughton and Simms. As regards latitudes the preliminary results only are given, for since the observations were made the whole of the stars have been reobserved on the meridian with the Cape transit circle. The origin of all the longitudes is the centre of the transit circle, and all the results depend upon signals exchanged with the Cape Observatory. The longitude of Durban was determined as part of the work in the telegraphic connection of the longitudes of Aden and the Cape: and observations of longitude were made at other places, as circumstances admitted, by Colonel Morris, Mr. Maclear, and Mr. Pett. Astronomical observations of azimuth were made at several of the principal stations, and the observed azimuths were referred to lines of the principal triangulation.

The survey, on the whole, appears to give results slightly in favour of Airy's elements of the earth as compared with Clarke's, but, as Dr. Gill remarks, this conclusion must be adopted with great reserve. For final results we must await the completion of Dr. Gill's original scheme.

Colonel Morris' Report contains a statement of the formulæ and methods of computation, with the auxiliary tables employed, which will be of the greatest use to Government surveyors in the colony; and his whole Report will be of great assistance to any one who has to conduct similar operations in other parts of the world. The Report is illustrated with excellent lithographic plates of the theodolites, the base-measuring apparatus, Comparateur, triangulation, &c., and the Government printers at the Cape have successfully carried out what must have been to them no easy task.

C. W. WILSON.

IN THE AUSTRALIAN BUSH AND ON THE COAST OF THE CORAL SEAS.[1]

PROF. RICHARD SEMON, of Jena, the author of the above volume, will be well known to biological readers in connection with the valuable monographs that, under the title of "Zoologische Forschungsreisen in Australien und dem Malayischen Archipel," have been produced by himself, Prof. Ernst Haeckel, E. von Martens, and other accomplished collaborators as the outcome of his travels and collections in the aforesaid regions during the years 1891–92.

The treatise under review is written in an essentially popular vein. It is a narrative of his voyage out to Australia; residence in and investigations conducted concerning the fauna of limited districts of that island continent; and of his homeward route, with a detour embracing New Guinea and a considerable area of Malaya. The larger section, associated with the title of "The Australian Bush," deals only with portions of the easternmost of the six Australian colonies, that of Queensland. The main object of Prof. Semon's expedition was the investigation of the embryological phenomena of those archaic zoological types peculiar to the Australian region. The lung-fish, *Ceratodus Forsteri*, and the monotrematous mammals Platypus and Echidna, whose unique, egg-laying habits were for the first time incontestably demonstrated some years since (1884) by our fellow-countryman, Mr. W. H. Caldwell. With this specified end in view, M. Semon proceeded to South Queensland and camped out for several weeks on the banks of the rivers Burnet and its tributary the Boyne, at some little distance from the townships of Gayndah and Coonambula. All three of the zoological types named are indigenous to this watershed (Ceratodus existing nowhere else), and by making liberal use of the assistance of the semi-civilised natives an abundant supply of the materials desired were obtained. While a few of the more salient developmental phases of Ceratodus and Echidna are figured in this volume, their detailed histological delineation and description are relegated to the monographs previously cited.

As the result of the first week's work, and the offered reward of half-a-crown for each female Echidna, one alone of the several natives engaged brought in as many as six of these monotremes, and a large assortment of other animals, altogether making good his claim for eleven shillings, after deducting rations. The outcome of the prompt payment of the rewards earned was somewhat disastrous. During Prof. Semon's absence from the camp the succeeding day, the natives contrived to exchange their hard cash for "fire-water" at the nearest hostelry—an undoubted breach of the regulations on the part of the vendor—and with the consequence that every man, woman and child, some thirty all told, were, on the learned Professor's return, dead drunk. A similar bacchanalian carouse, with threatened hostilities among themselves, is recorded as having followed the payment of the yet more liberal prize of 100 marks (£5), that was awarded to the first of the band of aborigines to bring in the ova of Ceratodus. In the case of such substantial sums being won by natives of such essentially child-like irresponsibility, the proper course would undoubtedly have been to have lodged the money for disbursal for their benefit in the hands of some one of the neighbouring responsible settlers.

In his brief reference to the life-habits of the Echidna, Prof. Semon places on record an interesting demonstration of the conspicuous homing instincts, and also of the travelling capabilities of the species. An example brought into the camp from a distance of no less than 6 kilometres, escaped in the night from the sack in which it was confined. A native following up its track, found it the following morning reposing in close vicinity to the spot where it was originally captured. The data chronicled, though apparently not from direct observation, concerning the food habits of the Echidna, in M. Semon's book, are somewhat at variance with those personally determined. It is here stated that worms and insects of all descriptions (Kerbtieren aller Art), though more particularly ants, constitute its normal pabulum. Also that ants, in the ordinary sense of the term, are devoured after the fashion peculiar to the typical ant-eaters, Myrmecophagidæ. With the several examples kept by the writer for long intervals, and which becoming tame were permitted to seek their nourishment in their native "bush," it was found that these Echidnæ not only limited their attention to ants, but in this connection cared only for the white succulent larvæ and pupæ or, so-called, eggs. Ants in their ordinary adult form, as in a teeming ant-track, would be altogether ignored. At the same time while consuming the larvæ, to gain access to which they tear open the hillocks, or overturn stones with their powerful claws, a considerable number of adult ants may be adventitiously injested.

The quest for the ova of Ceratodus proved to be a more lengthened task. No less than eight months were occupied in obtaining an accurate knowledge of that animal's spawning season, and in registering the developmental features of the ova when obtained. The persevering search, coupled with the handsome reward offered to the natives previously recorded, resulted in the ultimate acquisition of an abundant supply of material,

[1] "Im Australischen Busch und an den Küsten des Korallenmeeres-Reiseerlebnisse und Beobachtungen eines Naturforschers in Australien, Neu-Guinea und den Molukken." Von Richard Semon. 8vo, pp. xiv + 556. Mit 85 Abbildungen und 4 Karten. (Leipsig: Wilhelm Engelmann, 1896.)

and from which, through the conservation of specimens in suitable receptacles in the adjacent stream, every essential developmental phase was successfully recorded. The time spent in waiting for the spawning of Ceratodus was fully occupied by Prof. Semon in accumulating zoological material of every available description. His book constitutes also a full and interesting narrative of his experiences as a "new chum," or novitiate in Australian bush life, together with an abundance of information on colonial matters generally, in so far as they relate to Queensland. In this manner his descriptions of the fauna and flora are liberally interspersed with popular accounts of cattle mustering and branding, meat freezing works, sugar and gold-mining industries, and even dissertations on sports and politics. The pages of Prof. Semon's volume abound with illustrations, photographs of his camping stations and their environments, of the semi-civilised natives in his employ, and the animals characteristic of the district. It is to be regretted, being as demonstrated an expert with the camera, he should, as is conspicuously evident, have contented himself with reproducing the portraits of the animal forms from mounted or preserved specimens only.

From Southern Queensland, Prof. Semon travelled northward, making a stay of some weeks in the plains and scrublands inland from Cooktown, intent on the collection of marsupial embryological material, and also at Thursday Island for the acquisition of the abundant marine zoological products of Torres Straits. The chapters devoted to these selected centres of investigation constitute, it might be added, a comprehensive gazetteer to the townships of the East Queensland coast. The nature and configuration of the associated coastline receives also a share of notice, including—although deterred by counter-attractions from devoting special attention to this subject—that phenomenal formation the Great Barrier Reef. Prof. Semon concludes his discussion of the Darwinian and newer theories that have been advanced concerning its origin, by a declaration (p. 273) altogether in favour of the Darwinian or subsidence interpretation, as applied not only to the Australian, but to most other Barrier and Atoll reef formations.

Leaving Australia and having visited New Guinea, M. Semon extends his travels to Java, Celebes and Ceram, devoting a considerable time at Amboyna to exploring and collecting in the life-teeming coral seas of that district. A special object of his ambition in these latitudes was the investigation of the developmental history of *Nautilus pompilius*. Unfortunately the time of his visit was not favourable for the acquisition of the desired material, the Nautili being then in deep water. Inquiries elicited the fact that it is only during the south-east monsoon, from May to September, that this Cephalopod enters the shallow coastal waters for the purpose of depositing its spawn. By leaving suitable materials for their conservation, a consignment of half-a-dozen examples of this, in the flesh, rarely-obtained species were subsequently remitted to M. Semon from Amboyna.

The latter portion of Prof. Semon's book abounds with admirable photographs of the characteristic landscapes of the tropical districts visited and described. Mingled with these are a few notable Oriental architectural and social scenes, that of the Javanese rock-hewn Buddhist temple of Boro Budor, shown in the accompanying illustration, being especially fine. With the exception, however, of a drawing of the Robber Crab (*Birgus latro*), no zoological subject is figured, and one is somewhat

Buddhist Temple of Boro Budor, Java.

disappointed that none of the many opportunities occurring were utilised of recording with the camera glimpses of the marine paradise and its wondrous inhabitants that are so abundantly discussed. Photographic replicas of coral scenes and their associated denizens have of late years been shown to be fairly easily attainable, and appeal more intelligibly to the comprehension of the lay reader than a wealth of descriptive text. This shortcoming notwithstanding, Prof. Semon's book may be recommended as a most readable and instructive one to all those to whom the Australian bush and coral strands are *terræ incognitæ*.

Should Prof. Semon contemplate another tropical Australian expedition, we would earnestly recommend him to provide himself with one of the simple mosquito tents, procurable at any of the northern ports. Armed with this device, the night of torture on the Jardine River, so graphically described at page 333 *et seq.*, would have been shorn of all its terrors, the shrill piping of the baffled enemy outside the canvas adding but a zest to the peaceful enjoyment of his otherwise vainly invoked repose.

W. SAVILLE-KENT.

THE READING, WRITING, AND ARITHMETIC OF THE NEOLITHIC TROGLODYTES.

A DISCOVERY of great interest has recently been made by M. Ed. Piette, and published by him in *l'Anthropologie* (Tome vii., 1896, p. 385). In a cave at Mas-d'Azil,[1] on the left bank of the Arise, in the Department of Ariège, he excavated a layer of pebbles that had been painted with peroxide of iron in various devices. These occurred above a deposit containing bones of the reindeer, red deer, aurochs, horse, &c., and below a cinder layer, in which were great quantities of a land-snail, *Helix memoralis*, which indicates a somewhat humid climate; above this were deposits, in which polished stone axes occurred, and also *Helix hortensis*, which suggests drier conditions.

The Quaternary Period, according to M. Piette, was divided into two eras—the end of the Glacial Period forming the dividing line.

The intermediate Transition Period commenced when the modern fauna had replaced the glacial fauna; it consisted of three phases: (1) the Cervian, when the implements were of the same form as those of the earlier Quaternary era, and when the hunters of the reindeer made harpoons and needles of reindeer bones, and engraved upon their antlers. The climate then ameliorated, as evidenced by the presence of trees, and the reindeer passed away; and (2) the Asylian phase, or the period of coloured pebbles occurred. By this time man had forgotten the arts of engraving and carving, and commenced to devote himself to cultivation, and painted quaint forms on rolled stones. (3) The Snail-shell phase indicated a warmer humid climate, when vegetation flourished, and man cultivated several kinds of fruit trees.[2] Although the last two layers belonged to the Neolithic Period, polished stone axes were not found in them, though they occurred at a higher level associated, as has been already stated, with *Helix hortensis*.

The ruddled pebbles are mostly rounded, oblong, and flattened pebbles of quartz or schist taken from the bed of the river. In some cases the whole surface is coloured, but most frequently a stone is marked on one or both sides with simple devices. Sometimes the margin of the pebble is painted so as to form a kind of border to the decoration (Figs. 3 and 5).

[1] A description of this remarkable tunnel-like cave was given by M. E. Cartailhac in *l'Anthropologie* (Tome ii., 1891, p. 141). This paper was illustrated by two figures of the cave itself, and by a plate of some of the painted pebbles.

[2] M. Piette has already published a paper on the cultivated plants of the Transition Period at Mas-d'Azil in *l'Anthropologie* (Tome vii., 1896, p. 1).

M. Piette classifies the devices as follows: numerals, symbols, pictographic signs, and alphabetical characters.

(1) *Numerals.*—A large number of stones were found with from one to eight lines (Figs. 1 and 2) running across them. These the author considers as indicating simple numerals. Never have more than eight lines been yet found on a stone. Some of the pebbles are marked with rounded or oval spots (Fig. 3). These are regarded as units of higher groups of figures—either nines, or more probably tens, and the Egyptian system is adduced as an argument in favour of this view. The spots vary in number, one stone bearing as many as twenty-three.

FIG. 1.

FIG. 2.

FIG. 3.

Occasionally marginal blotches were painted. The author's enthusiasm has led him to speculate whether these may not be the squares of the higher grade units; thus, a pebble (Fig. 4) with twelve marginal blotches and six central spots is credited with indicating a total of 1260 in the decimal system; or 1728+60, that is, 1788 on a duodecimal hypothesis. It apparently strikes even M. Piette that these are rather high numbers for the Neolithic troglodytes, and so he suggests that there may be no significant difference between central or marginal spots. As a disc surrounded by a circle has during all

FIG. 4.

FIG. 5.

time been considered as the symbol of the sun or of a sun deity, the question is asked, "May not the circles in lines be signs employed in a hieratic writing?" Amongst other suggestions, he speculates whether they may not be meant to denote objects of special value; and, lastly, he seriously proposes the view that these very abundant numeral stones may have been counters in some game. Occasionally these "numerals" are ornamented, as in Fig. 5.

(2) *Symbols.*—M. Piette candidly admits that the conclusions of the "perilous study" of symbolism should

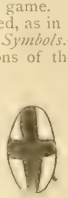

FIG. 7.

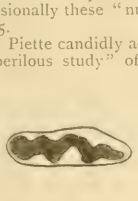

FIG. 8.

FIG. 9.

be stated with the greatest reserve. Crosses, especially the equilateral cross (Fig. 7), are abundant, but the *tau* (Fig. 6) also occurs. We need not follow the speculations to which such designs irresistibly lead.

(3) *Pictographic Signs.*—Serpentine designs (Fig. 8) often occur, and M. Piette gives two personal anecdotes to illustrate the persistence of a superstitious regard for snakes in the Pyrenees and in the Department of Aisne. Other identifications are more doubtful, as, for instance, "trees" (Fig. 9), "reeds," &c.

(4) *Alphabetical Characters.*—The most startling section of this memoir is the suggestion that certain designs

painted on some of the pebbles indicate entirely conventionalised phonetic characters. Most of them are isolated markings, as in Fig. 10, which resembles the Greek Π and the Cypriot *go*. In a very few instances two or more symbols are associated together, as in Fig. 11. This is, as a matter of fact, the nearest approach to an inscription. M. Piette makes full use of the recent discoveries of Mr. Arthur J. Evans in early Mediterranean scripts, and we must leave it to experts to discuss the problems opened up by M. Piette's astonishing discoveries. Assuming these markings to be syllabic signs, can it be possible that these pebbles were employed in building up words and sentences, much as children use boxes of letters? The author states that "thirteen out of twenty-three Phœnician characters were equally Asylian graphic signs."

FIG. 10.

FIG. 11.

No longer can markings or designs, made by savage or primitive peoples, be ignored or be superciliously smiled upon as of no moment. We now recognise that such peoples do not while away their idle hours in making meaningless cabalistic signs, or in aimlessly decorating objects. When one looks through the twenty-five beautifully coloured plates of the atlas that accompanies this memoir, the belief is irresistible that these hundreds of pebbles have not wantonly been painted, but that thereon is recorded a hitherto unsuspected phase of prehistoric culture. At times one may feel a little good-natured amusement at the ingenuity displayed by M. Piette; but, at the same time, we respect his enthusiasm, and trust that he may be fortunate enough to bring further evidence to light. A. C. H.

EMIL DU BOIS-REYMOND.

AS was stated in our last issue, Emil du Bois-Reymond, Professor of Physiology in the University of Berlin, and Perpetual Secretary of the Berlin Academy, died on December 26, after a severe illness.

He was born in Berlin on November 7, 1818, where his father, who had begun life as a watchmaker in Neuchatel, had attained an important position. His mother was of Huguenot descent, her family having been driven out of their native country in the seventeenth century. He received his early education at the Collége Français at Berlin, and subsequently at the College of Neuchatel. He entered the university at Berlin when he was eighteen years of age, and was matriculated in the Philosophical Faculty.

At the outset of his university career his pursuits would appear to have been eclectic, for it is stated that he attended Neander's lectures, and was much interested in theology; but about 1837 he took to the serious studies of his life. After a year or two devoted to mathematics, physics and chemistry, he became a pupil of the illustrious J. Müller, and eventually his assistant. In 1841, he was asked by his chief to repeat the observations of Matteucci in his essay "Sur les phénomènes électriques des animaux," which had been published the year before in Paris. This led to the historical studies which he embodied in his dissertation for the degree of D.M. ("Quae apud veteres de piscibus electricis exstant argumenta"), and to the discovery of the main facts of what we now call electro-physiology. His first research on this subject was published in the fifty-eighth volume of *Poggendorff's Annalen*, under the title, "Ueber den sogenannten Froschstrom und über die elektromotorischen Fische." During the next ten years he devoted himself entirely to the line of inquiry he had determined to follow. The fruits of his labour were embodied, not in separate papers, but in his great work on "Animal Electricity," which was not completed till about ten years ago, although the first volume appeared in 1848. When, in 1855, he visited London, he had already acquired a European reputation. Some readers may, perhaps, remember the interest excited by a Friday evening lecture, with demonstrative experiments, which he gave at that time at the Royal Institution. In 1858 he succeeded Müller as Professor of Physiology at Berlin, and in 1867 became Secretary of the Berlin Academy. After the Franco-German war the palatial building in the Neue Wilhelmstrasse was erected according to plans which, with much forethought, he had designed, so as to provide for all the branches of physiological teaching and research. These were carried out with a completeness which has made the Berlin laboratory a model for similar institutions in all parts of the world.

About 1878 du Bois-Reymond published his "Collected Papers," in which all the scientific work done by him up to that time is included, excepting what had been recorded in the "Thierische Elektricitat," and in 1881 a volume appeared, shortly after the accident which deprived his assistant, Dr. Sachs, of his life, containing the results of Sachs' experimental investigations of the *Gymnotus electricus* in its native country.

To many readers who have no special interest in the scientific problems which it was the aim of his life to solve, du Bois-Reymond is known by his contributions to literature, and by the admirable literary style of his essays. Of his numerous writings on historical, biographical, and philosophical subjects, we can mention only the best known, such as (1) the historical introduction contained in the first chapters of his great work; (2) the essay on university organisation (1870); (3) on present and past of physiological teaching, and on the relations of natural history to natural science (1878); and (4) on the limits of natural knowledge (1882).

Du Bois-Reymond's life-work was the investigation of the electrical phenomena of animals and plants, and the relation between them and the vital endowments of the structures in which they manifest themselves. The first part of this task he accomplished all but perfectly. As regards the second, he arrived at theoretical conceptions which, although no longer so predominant as they were, still serve as points of departure in all electro-physiological discussions. To exemplify this, we must go back for a moment to the time fifty years ago, when he undertook the experimental criticism of Matteucci's work. Recognising that the electrical properties which had been described by his predecessors with relation to the whole organism could only be understood by referring them to the parts in which they manifested themselves, he at once limited his inquiry to the electromotive properties of the muscles, choosing for his purpose those of simplest construction—those which consist of parallel fibres. Considering that in such a muscle each fibre must be an epitome of the whole, and that if it were possible to break up a fibre into its constituent fibrils, its properties would also represent those of the whole, and having found experimentally that the surface of a cylinder obtained from a living cylindrical bundle of fibres by cutting it across in two places, exhibited in different parts differences of potential which could be expressed by a very simple law (the so-called law of the muscle current, according to which the centre of each cut surface is negative to every other part), it required but little use of the scientific imagination to suppose that if the cylinder contained elements of indefinite minuteness endowed with properties corresponding to its own, the result would

be as observed. He thus arrived at the theory of electromotive molecules which, with extraordinary insight and thoroughness, he worked out in its relations to all the electromotive phenomena of nerve and muscle when in the unexcited state. But, in doing this, he met with unexpected difficulties. So long as his observations were limited to the properties of the muscle cylinder the theory was applicable; a model could even be constructed of schematic molecules which displayed all the phenomena of the "cylinder" of living muscle; but in the natural muscle certain "parelectronomic" facts, to use du Bois-Reymond's word, presented themselves, which to this day are irreconcileable.

In connection with the molecular theory of the muscle current, he discovered the elementary facts relating to what is called stimulation or excitation, viz. that when a muscle is excited, whether naturally or artificially, the sudden shortening of its fibres is ushered in by still more sudden electrical changes. This phenomenon du Bois-Reymond succeeded in connecting with those of the muscle cylinder by means of the theory above referred to. According to his view, when a muscle is excited, each of its electromotive elements sustains a diminution of its E.M.F., the result of which is that in the muscle cylinder so excited the pre-existing difference between its cut-surface and its natural surface diminishes. Here again the progress of investigation has shown that while some of the electrical phenomena of excitation require such a theory for their explanation, it does not cover the whole ground; for which reason many physiologists decline to assign to it its true value.

A third theory of very wide application relates to the way in which electric currents when used as stimuli act on nerves. It was recognised by du Bois-Reymond that a voltaic current led through a nerve, although it produces those remarkable changes in its electromotive properties which are called electrotonic, fails to excite it to action so long as the current strength remains constant, but that the slightest increase or diminution of current strength excites it with an intensity which is inversely proportional to the time occupied by the change. Under certain conditions he found that his experimental results were in such strict conformity with the principle laid down as to justify their being embodied in a mathematical formula. But even here we now know that this "law of excitation" is not of universal application.

We have referred to these instances for the purpose of pointing out that du Bois-Reymond's real greatness consisted, not in his theories, but in the exactitude of his observations, the excellence of the methods which he devised, and the number of new relations which he discovered between physical and vital phenomena. Just as Ludwig taught us how to investigate the mechanics of the circulation, and Helmholtz how to determine the time-relations of physiological processes of very short duration, so du Bois-Reymond not only opened to us a new field of investigation, but furnished his contemporaries and successors with the means of cultivating it. For this service we can best show our gratitude by striving to work as he did, never allowing theory to influence our judgment in the interpretation of experimental data, and never contenting ourselves with inadequate methods of observation. In investigations of such difficulty mistakes are unavoidable, and it cannot be asserted that in his fifty years of active work du Bois-Reymond never fell into any errors of observation; but if we compare these with the new truths which he brought to light and established, their importance seems indeed trivial. There can be no more striking proof of the solidity of his achievements than the fact that, notwithstanding the large number of active workers who, during the last few decades, have been engaged in physiological researches, the instruments and methods which he devised are still in use. In every laboratory you find his "Schlitten inductorium," his non-polarisable electrodes, the du Bois key, and the du Bois compensator.

Like other great teachers, du Bois-Reymond founded a school; although his pupils were far from being as numerous as those of Ludwig, they occupy very important academical positions. The man who probably has done more to maintain the influence of his doctrines than any other is Prof. Bernstein, of Halle, whose "Untersuchung über den Erregungsvorgang," published in 1871, was comparable in importance to that of Hermann's research on muscle physiology, published a few years earlier. It is noteworthy that each of them dedicated his research to du Bois-Reymond—the one afterwards to become his energetic opponent, the other then and now his cordial supporter. If on any one the mantle of du Bois-Reymond falls, it must be on Bernstein.

J. BURDON-SANDERSON.

NOTES.

THE elevation of Sir Joseph Lister to the Peerage is a New Year's honour which has been received with the keenest satisfaction in the scientific world. It may be taken as an acknowledgment by the Crown of the high position of the President of the Royal Society, as well as a recognition of the life-long work in science which led to Sir Joseph Lister's selection for that honoured Presidency.

AN address of congratulation, signed by a number of eminent men of science, and by leaders in other branches of learning, has been presented to Mr. Herbert Spencer, in recognition of the successful completion of his "System of Synthetic Philosophy." With reference to this work it is remarked in the address: "Not all of us agreeing in equal measure with its conclusions, we are all at one in our estimate of the great intellectual powers it exhibits, and of the immense effect it has produced in the history of thought." The signatories requested Mr. Spencer to permit them to employ some eminent artist to take his portrait, with a view to its being deposited in one of the national collections. Though at one time averse to a proposal of this kind, Mr. Spencer has now given his consent in a letter to Sir Joseph Hooker, who forwarded the address, and Mr. Herkomer, R.A., has undertaken to paint the portrait. It is gratifying to know that the country will possess an authentic personal likeness of so distinguished a philosopher. Donations for the portrait fund may be sent to the Bank of England, Burlington Gardens, W.

THE distinguished Berlin astronomer, Prof. Dr. Arthur Auwers, has received from the German Emperor a gold medal for his services to science.

M. CALLANDREAU, professor of astronomy at the Paris École Polytechnique, has been elected a Correspondant of the St. Petersburg Academy of Sciences.

THE Council of the British Institute of Public Health have awarded the Harben medal for 1897 to Prof. M. von Pettenkofer, Emeritus Professor of Hygiene in the University of Munich.

IT is understood that Mr. Herbert Goss and the Rev. Canon Fowler, who have been joint Secretaries of the Entomological Society for the past eleven years, do not intend to offer themselves for re-election at the next annual meeting of the Society on the 20th inst.

WE regret to announce the deaths of Dr. Luigi Calori, professor of anatomy in Bologna University; Dr. G. D. E. Weyer, professor of mathematics and astronomy in the University of Kiel; M. Vivien de St. Martin, renowned for his researches in ancient geography; and Mr. Theodore Wormley, of Philadelphia, well known as a chemist.

M. GASTON TISSANDIER, who for the last quarter of a century has presided over the destinies of *La Nature*, has just retired from the editorship, and M. Henri de Parville has succeeded him. It is not proposed to make any changes in the character of the journal, and the traditions which have secured for *La Nature* a high degree of success and prosperity will be followed by the new editor.

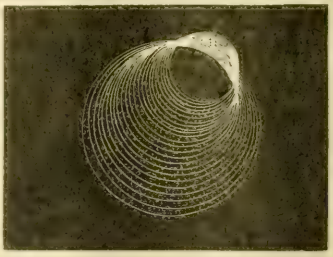
BY leaving almost the whole of his fortune to be converted into an international fund for the advancement of scientific research, the late M. Alfred Nobel performed an act for which his memory will be cherished in the world of science. According to the terms of the will, as reported by Reuter's correspondent at Stockholm, a fund is to be formed from all his realisable property, the yearly interest from which is to be divided into five equal portions. The first of these is to be allotted as a prize for the most important discovery in the domain of physics. The second is for the principal chemical discovery or improvement. The third is for the chief discovery in physiology or medicine. The fourth is for the most distinguished literary contribution in the same field; while the fifth is to be allotted to whomsoever may have achieved the most, or done the best to promote the cause of peace. All these prizes are open to Scandinavians and foreigners alike. After a few bequests to individuals have been deducted, it is expected that the fund thus devised will amount to the sum of 35,000,000 kroner, or nearly two millions sterling. The result of this very generous endowment to science will be an ever-growing monument to M. Nobel, built up of contributions to natural knowledge; a monument, too, which will stand out as a testimony of broad-mindedness and devotion to science. M. Nobel was cosmopolitan in more ways than one, for he was the master of seven or eight languages. He was a Swede by birth, having been born at Stockholm in 1833. A very appreciative article in the *Ardrossan and Saltcoats Herald* of December 25, evidently written with authority, contains a list of his researches and inventions, and some interesting notes on his personal characteristics. M. Nobel was educated at St. Petersburg, and subsequently assisted his father in his engineering shops at Stockholm, and was little over thirty years of age when he became identified largely with explosives. On May 7, 1867, he published his great "Dynamite, or Nobel's Safety Powder" paper, which inaugurated a new era in the entire world of explosives, and in many branches of engineering. His blasting gelatine patent followed in 1875; and the invention of Ballistite, a smokeless propelling powder, was patented in 1888. M. Nobel was never married.

WE are glad to announce another gift to science. The Paris correspondent of the *Times* states that the widow of Baron Maurice Hirsch, of Vienna, has resolved to present 2,000,000 francs to the Pasteur Institute as a memorial of her husband. This will enable the building to be enlarged by chemical and biological laboratories, which, it is estimated, will cost 800,000 francs. Some of the professors, moreover, at present receive little or no salary. The gift comes at a very appropriate time, and it could not have been bestowed upon a worthier object, nor could a better memorial be found, than the Pasteur Institute.

THE twenty-fourth annual dinner of the old students of the Royal School of Mines will be held at seven o'clock on Tuesday, January 26, at the Criterion Restaurant. The chair will be taken by Dr. T. K. Rose. Tickets may be obtained from Mr. H. G. Graves, 5 Robert Street, Adelphi, W.C.

QUITE recently a considerable number of additions to our knowledge of the Röntgen rays and their applications have been published. From Prof. Hobday we have just received a reprint of his and Mr. V. E. Johnson's joint paper in the *Veterinarian* for September, dealing with the use of these rays in veterinary practice, illustrated by several excellent radiographs of the hoof and hock of horses, both normal and abnormal. In the *Bulletin* of the Belgian Royal Academy, M. L. N. Vandevyver enunciates the empirical law that the length of exposure for radiographs through limbs of different dimensions varies as the cube of their thickness, and the illustrations which accompany the paper afford ample corroboration of the law from a practical point of view. The *Journal of the Camera Club* for December contains the account of a lecture, by Prof. Rücker, on the transparency of glass and porcelain to these rays, from which it appears that the presence of phosphates in china is indicated by their greater opacity, a result which might naturally be expected to follow from the considerable opacity of bone to Röntgen rays. M. Bouchard, in a communication to the Paris Académie des Sciences, states that Röntgen rays can be successfully employed in diagnosing pleurisy and similar complaints.

A CURIOUS optical phenomenon is exhibited by the accompanying tracing, made by a finely-pointed top spinning on a plate of glass covered by a light coat of lampblack, and sent to us by Dr. C. B. Warring. If the spiral is looked at with either eye, the other being closed, one seems to see the inside of a hollow truncated cone, the smaller base being farthermost; or else only the outside will be seen, the smaller base being



apparently nearest. If the eyes be opened and closed alternately, the image may appear to each in the same position, perhaps for half-a-dozen alternations, and then, without apparent cause, reverse, or it may reverse for one eye and not for the other. If both eyes be opened, only one image may appear, sometimes in one position and sometimes in the other. The principle seems to be the same as that which applies to a polished hemisphere laid on a plane surface, and looked at from a little distance.

AT a meeting of the Société Française de Physique, on December 4, M. Jean Perrin described his investigations on the dissociation of neutral electricity produced in gases by Röntgen rays, to which their power of discharging insulated conductors is due. At constant temperature the quantity of dissociated electricity per unit volume is *ceteris paribus* proportional to the pressure, and hence to the density of the gas. At constant pressure it is independent of the temperature, and since the density is inversely proportional to the absolute temperature, it follows that the quantity dissociated per unit mass is independent of the pressure, and varies as the absolute temperature. At the same meeting, M. Broca made some interesting statements about the baldness produced by Röntgen rays, which is caused by the hairs falling off with the skin. The scars are sometimes not produced till three weeks after the skin was exposed to the rays, and where the cuticle is replaced by cicatrised tissue the hairs disappear; but they grow up again everywhere else, so that the rays cannot be used for depilatory purposes.

THE influence of light upon the discharge of electrified bodies has formed the subject of many investigations since Hertz observed the effect of ultra-violet light upon the spark of an induction coil, less than ten years ago. Since then an extensive literature of the subject has grown up, though only a few of the more important papers are in English; so it is difficult to determine how far the knowledge of the phenomenon has progressed. For this reason, and in view of the evident importance of the subject, Mr. Ernest Merritt has prepared an account of the investigations which have thus far been published; his very useful summary appearing in *Science* of December 11 and December 18, 1896. It appears from this account that a thoroughly satisfactory explanation of the discharging action of light has not yet been found, and that many questions concerning the phenomenon remain to be settled by further experimental investigation.

THE January number of *Science Progress* opens with an article, by Prof. H. A. Miers, F.R.S., on Dr. Lehmann's "Liquid Crystals." Two of these remarkable bodies are azoxyphenol and azoxyanisol. When crystals of azoxyphenol are warmed on a microscopic slide, they are suddenly transformed, at a temperature of 134°, into a substance which preserves the outline of the crystal, is strikingly doubly-refractive, and behaves like a true crystal when rotated between crossed Nicols, but is nevertheless a liquid. If the preparation be still further warmed, it passes at 165° into a third modification which is also liquid, but not doubly-refractive. It is possible to contrive that this molten substance shall contain small portions of the first, birefringent, liquid which float about in it as perfectly spherical drops, and are regarded by Lehmann as really liquid crystals. Crystals of azoxyphenol behave in a similar way, the changes taking place at 116° and 134°. The investigation of these curious birefringent liquids has an important bearing upon current views regarding the structure of solids and liquids.

BALMOKAND, a cloth-seller of Rawalpindi, has written a remarkable brochure, entitled "The Priceless Gem" (The Mitra Vilasa Press, Lahore), which advocates what may be regarded as a "puritanical" movement in modern Hinduism. It would be easy to indite a cheap criticism of the literary style, the authorities quoted, and of the translation from the original Urdu into "baboo" English, but it is a more grateful task to recognise and make known the serious aim of the author. Being struck by the contrast between the former learning, wealth and power of ancient India, and her present "ignorance, indolence, indulgence . . . with all other vices and evils," Balmokand, by "long contemplation and continuous thought," came to the conclusion that this is due to disregard of the ancient *Baran* custom; by which a man and woman of similar *baran* being joined in marriage "should become for their whole life a loving and affectionate couple." The author waxes eloquent on the joys of a happy marriage, and on the chivalrous protection, courtesy and deference that is due to woman from man, and sustains his position by quotations from the Hindu sacred writings. He is also strong on the crime of infant marriage, and relies on ancient authority for maintaining that neither sex should marry before the twenty-fifth or twenty-sixth year. Most of the ills of modern India are ascribed to the breaking up into innumerable castes of the four primitive *barans*—Brahmin, Kshatrya, Vaisha and Sudra. The psychological and religious tendencies of the members of the four *barans* are described, and the decadent social groups produced by various degrees of miscegenation are detailed. The four primitive castes were communities of relationship; he would resuscitate the classes, but would admit entrance into them by the casting of a horoscope. The selection of suitable partners in life is rightly regarded as a most important matter which affects family happiness and the well-being of the next generation: this selection is, however, not to be made by wise consideration in the European sense of the term, but, like all the other events of life, is to be determined by divination. The main interest of the pamphlet lies in the picture that it gives of the working of the mind of an enthusiast and visionary belonging to an entirely different world from our own; it is a practical lesson in comparative psychology.

A GRAVE-FIND at Vitzke, in Altmark, probably belonging to about the end of the fourth century of our era, is described and figured by E. Krause in *Globus* (Band lxx. Nr. 17). In the same number of the journal is the annotated translation (in German) of the Polynesian song of the saving of Nga-Upoko-E-Rua, the daughter of Potikitanas, in which are embodied myths of origin. Dr. A. Vierkandt follows with a sociological study on the family. The succeeding number of *Globus* has an illustrated article showing the skill in portraiture of the ancient Egyptian sculptors. P. Dittrich contributes a study of the plans of houses and of rudimentary courtyards in Schlesien. Schlesien was originally a German land; during the wandering of the peoples it was peopled by Slavs, but later, especially in the west, German influence made itself felt. It is not too soon that such investigations have been undertaken, for the thrashing-machine is replacing the flail, and gradually the history of the old culture will become obliterated. Would that we had such investigations in our own islands!

SOME experiments have been made by Wernicke on the vitality of cholera vibrios under particularly interesting conditions. A model aquarium was constructed, and in it water-weeds of all descriptions were planted; it was supplied with fish, and there was no lack of ordinary water bacteria, in addition to which about five milliards of cholera germs were introduced. The vessel and its contents stood in the laboratory, and was exposed to both diffused light as well as to direct sunshine. Nearly three months after the cholera vibrios had been added, they could be detected in the water, as also on the water-weeds; whilst even after the lapse of three months they were isolated from the mud at the bottom. Later, however, all traces of them disappeared. Wernicke is of opinion that mud affords a very suitable nidus for the preservation of cholera vibrios, and believes that, had he allowed less light to gain access to his glass vessel and its contents, he would have identified them even longer; doubtless in the beds of rivers they would preserve their vitality for a considerably longer period. No alteration, either in their morphological or biological functions, could be traced in these cholera vibrios in consequence of their surroundings; but whilst Wernicke states that they were highly virulent when they were first introduced, he unfortunately omits to say if their pathogenic properties suffered any diminution in the interval.

"THE principal household insects of the United States" are described by L. O. Howard and C. L. Marlatt in *Bulletin* No. 4, published by the United States Department of Agriculture. The work contains numerous original observations, and will interest the European reader by giving him a clear and trustworthy account of some of the insect pests which infest houses in the Southern States of America. Among the insects which are equally well known in Europe and America is the bed-bug, which Prof. Marlatt informs us was said by Kalm in 1748 to be plentiful in the English colonies and in Canada, though unknown among the Indians. We believe there is evidence of its having been abundant in Jamaica early in the last century. Prof. Marlatt thinks that the irritation caused by its attacks is due simply to the puncture, and that no poison is injected; but this is certainly an open question, and requires further investigation. A far more formidable insect, however, is *Conorhinus sanguisuga*, Leconte, called by

Marlatt "the blood-sucking cone-nose," a near ally of the well-known Chilian Bug, *C. Renggeri*, and very similar in its habits, attacking insects and vertebrate animals almost indiscriminately. It belongs to the same family as our Wheel Bug (*Reduvius personatus*), and, like the latter insect, is common in outhouses, and will, on occasion, feed on the common bed-bug. Our insect, however, is much smaller, and rarely attacks man. American houses are also commonly infested by a curious long-legged centipede, *Scutigera forceps*, belonging to a family represented in South Europe, though not in England. However, it only seems to bite in self-defence, and is therefore a less objectionable visitor than might be supposed. White ants, which have, happily, not yet effected a lodgment in England, are as destructive in America as in many other parts of the world; but are too well known to need special notice here. Much more interesting matter will be found in this important little *Bulletin*.

"VERITYS' Conversion Table" (designed by Mr. M. B. Cotterell) shows graphically the prices of wire and cable per yard, coil, or mile. By means of this simple diagram, it is easy to find the price per coil and per yard of a cable quoted at any price per mile. Every maker of electrical fittings should hang up a copy of the diagram in his office, for as a ready reckoner it will prove very serviceable.

A THIRD edition of "Our Secret Friends and Foes," by Dr. Percy Frankland, F.R.S., published in the S.P.C.K. Romance of Science Series, is now in the press, and will shortly be issued. A new chapter has been added, in which diphtheria-antitoxin is dealt with, as well as Calmette's investigations on snake poisons and their treatment by anti-venomous serum. Dr. Nobbe's recent researches on root-nodule bacteria are described in detail, whilst milk-bacteriology in its latest developments is also enlarged upon.

UNDER the editorship of Dr. J. H. Bechhold, a new German weekly journal—*Die Umschau*—has made its appearance. It is proposed to survey the developments and advances of pure and applied science, literature and art, by interesting articles and notes. The first number of the new periodical contains among the articles, "Völkerkunde," by Dr. Max Buchner; "Die Physik der Himmelskörper," by Dr. Huggins, put into German by Marie Bechhold; and "Die Heimat der Germanen," by Dr. J. W. Bruinier.

TWO considerable additions have recently been made to the literature of limnology. In the *Mittheilungen der k.k. Geographischen Gesellschaft* of Vienna, Herr Eberhard Fugger publishes a paper on mountain lakes, which is for the most part a summing-up of conclusions based on extensive observations made on the lakes of Salzburg and the High Tauern during 1891, 1893, and 1895. The causes of origin of such basins are discussed in detail, and their life-history traced through various stages either of continued extension by erosive action, or of gradual filling up. The typical rock-basin is to be regarded as an interruption of the work of forming a valley.

IN the above-named journal Dr. K. Peuker draws attention to the work of Dr. W. Halbfass on the lakes of Northern Germany, especially the Arendsee and the lakes of the Elbe basin. The Arendsee is found to be the deepest lake known in Northern Germany, its mean depth from 1200 soundings being 29·3 metres, and greatest depth 49·5 metres. The extreme concavity of the basin serves to account for remarkable variations in the temperature of the water.

THE ninth edition of the list of vertebrated animals now or lately living in the Gardens of the Zoological Society of London has just been published by the Society. It constitutes "a nearly complete catalogue of all the species of vertebrates of which specimens have been exhibited in the Society's menagerie during the past thirty-four years." The first edition of the list was issued in 1862, and it contained 100 pages and comprised 682 species. The present edition runs into more than 700 pages, and contains references to 3044 species, 770 of which are mammals, 1676 birds, 420 reptiles, 80 batrachians, and 98 fishes. There are also seventy woodcuts in the volume. The list is of service not merely as an indication of the animals which have been kept in the Society's Gardens, but also for references to descriptions of them.

WE have received from Prof. Sresnevsky, Director of Dorpat Observatory, an excerpt paper upon the greater oscillations of barometric pressure during the year 1887. The investigation has been undertaken in the interest of weather prediction. It is well known that successful weather forecasting depends chiefly upon the prediction of the direction which the centre of an atmospheric disturbance will follow. There are various indications which sometimes allow of the determination of this path, but many of the rules are of an empirical nature. The author has investigated these indications by means of the observations published in the Russian Weather Reports, and has embodied the results at which he has arrived in a useful communication to the *Bulletin* of the Imperial Society of Naturalists of Moscow.

THE Government Observatory, Bombay, has just issued its thirty-fourth volume, containing the results of the magnetical and meteorological observations for the year 1895. This institution has kept up an uninterrupted record of systematic and trustworthy magnetic and meteorological observations for the last fifty years, and the results are condensed in a valuable appendix to the present volume. The maximum temperature recorded during this period was 100·2° in 1857, and the minimum 53·3° in 1847. The average yearly rainfall is 72·44 inches, and the annual values vary from about 41 inches to 115 inches. The maximum fall in one day amounted to 16 inches, in June 1886. The Observatory owes much of its present reputation to the valuable contributions in terrestrial magnetism and meteorology of Mr. Charles Chambers, the late Director. We notice that, with the exception of Mr. Moos, the present Director, the staff is composed of native assistants.

THE General Report on the operations of the Survey of India during the year ending with September 1895, has just been received. In this period the aggregate area surveyed on all scales amounts to 125,384 miles, exclusive of 5018 square miles embraced by traverse operations in the Central Provinces and the North-western Provinces and Oudh. In the trigonometrical surveys, the Upper Burma principal triangulation was carried northwards as well as westwards through Manipur and Assam. In addition to the topographical work accomplished during the year, a detachment with the Pamir Commission surveyed 250 square miles, and one with the Chitral Relief Force surveyed in detail 450 square miles on the 1-inch scale, 215 square miles on the ½-inch scale, and, approximately, 1900 square miles on the ¼-inch scale. The results of the operations of the latter surveyors is that considerable knowledge of the topography has been gained of an area of 3600 square miles of a country previously practically unknown, and much credit is due to Captain Bythell and the men who served under him for such a satisfactory record of work. Two views, representing the Malakand Pass and the Chitral bridge and fort, have been reproduced by heliogravure to illustrate Captain Bythell's report. A mass of information on the forest survey operations, cadastral surveys, traverse surveys, longitude observations, geographical surveys and reconnaissances, carried out by the Survey Department under the direction of Colonel C. Strahan, R.E., Surveyor-General of India, is included in the General Report.

SEVERAL Bibliographies, lately received, show that serious and increased attention is being given to the organisation of scientific literature. One admirable and very useful work of this kind is a "Catalogue des Bibliographies Géologiques," prepared under the direction of M. Emm. de Margerie, Secretary of the Commission Internationale de Bibliographie Géologique, in conformity with a vote taken during the International Congress at Washington in 1891. The volume is chiefly made up of descriptive lists of publications arranged according to regions, those in each region being in turn classified according to subjects and authors. The contents fill 732 pages. The work is primarily intended for distribution among members of the Geological Congress; so only a few copies are for sale, these being obtainable from either Messrs. Dulau or Messrs. Friedländer. As expressed by the title, it is not a bibliography of geology, but a bibliography of geological bibliographies, using this latter designation in its widest sense. The volume may thus be regarded as the key to geological literature, and it will doubtless prove of great service as the means by which geologists will be able to unlock their stores of knowledge.—The second volume of the "Bibliotheca Geographica," prepared by Herr Otto Baschin, and issued by the Gesellschaft für Erdkunde zu Berlin, has also come to hand. The plan of the work, which refers to the geographical publications of the year 1893, is the same as that of the first volume, except for a few minor changes in the system of classification; but while the previous volume contained 13,800 entries for the years 1891 and 1892, the present has over 10,000 for 1893 alone. Herr Baschin invites the authors of geographical papers published in journals, and in Transactions not restricted to that branch of science, to forward full titles and references to him at "Schinkelplatz 6, Berlin, W."—A répertoire of physiological works published in 1895, has been prepared by Prof. Ch. Richet. In this "Bibliographia Physiologica" (Paris: Felix Alcan) the publications are classified according to Dewey's decimal system, and Prof. Richet urges authors to give their papers numbers based upon this plan. It is proposed to publish very shortly similar bibliographies of physiology for 1893 and 1894. The first part of the bibliography for 1896 was received a few days ago. Authors are requested to send copies of memoirs on physiological subjects to Prof. Ch. Richet, Faculté de médecine de Paris, and so assist to make his catalogues as complete as possible.

THE additions to the Zoological Society's Gardens during the past week include a West African Love Bird (*Agapornis pullaria*) from West Africa, presented by Miss E. M. Tuely; eight Grooved Tortoises (*Testudo calcarata*) from South Africa, a Bearded Lizard (*Amphibolurus barbatus*), seven —— Lizards (*Amphibolurus*, sp. inc.), two Great Cyclodus (*Tiliqua gigas*), six Lesueur's Water Lizards (*Physignathus lesueuri*), a Death Adder (*Acanthopis antarcticus*), a Purplish Death Adder (*Pseudechis porphyriacus*), a Short Death Adder (*Brachyaspis curta*), three Brown Death Adders (*Diemenia textilis*) from Australia, deposited.

OUR ASTRONOMICAL COLUMN.

THE TOTAL SOLAR ECLIPSE OF AUGUST 9, 1896.—M. Deslandres, who was commissioned by the Bureau des Longitudes to proceed to Japan and make observations of the total solar eclipse visible there on August 9 last year, gives in *La Nature* for December 26 a short account of the expedition in general and a brief description of the results obtained. The station decided upon was the small port known as Yesashi, on the northern side of the island of Yézo, where the Japanese party under Prof. Terao and the American expedition were eventually located. During their stay of six weeks there were only eight fine days, so that the previous meteorological reports, which indicated the bad climatic conditions of the island at this season, were entirely corroborated. As we all know, the sky was cloudy during the time of totality, but the French party was more fortunate than the Norwegian observers, for their clouds were evidently not so dense as those which obscured the sun at Vadsö and Kiö. M. Deslandres, who was directing the observers under him, saw at a glance that it was useless to proceed in the programme previously arranged for under fine weather conditions. He therefore gave instructions that in the different instruments a single sensitive plate should be exposed for the entire duration of totality. Of the plates exposed, six showed the corona "plus ou moins fort," while on the remainder nothing was seen after development. The negatives indicated dim extensions in the north-west, north-east, and south-west directions, but practically only the general distribution of the coronal light was shown. The images of Venus and Jupiter were also found recorded on two of the negatives. The eclipse of 1896, as M. Deslandres says, confirms the following law, indicated already to a certain extent in previous eclipses, namely, that the periodical variations of the spots which are followed by the prominences extend to the corona, and therefore also to the entire solar atmosphere.

THE MELBOURNE OBSERVATORY.—The thirtieth report (May 1895–June 1896) of the Board of Visitors to the Melbourne Observatory, shows that since the large reduction of the staff which has taken place during the last two or three years, the work of the observatory has had to be necessarily limited. Mr. Baracchi, who is the acting astronomer, has nevertheless been able to cope with the existing circumstances and carry on, at any rate, the most important work and supply the local requirements for meteorological statistics and other scientific matters. Reference is also made in this report to the existence of a large amount of valuable work which is yet unpublished. Besides over thirty years' records in terrestrial magnetism and valuable investigations bearing on the climate of the colony, there is the important work of measurement of the photographic plates of southern zone stars, which is the Melbourne portion of the great international undertaking of the photographic chart of the heavens. There seems also to be a great mass of material unpublished concerning the work done with the great reflector; this consists, as we are told, of finished drawings of nebulæ, sketches, notes, and micrometric measurements "only a minute portion of which has been published." It is sad to read that "observations with the great telescope and other equatorials must for the present be abandoned, and that even if the extra assistance asked for be granted, we shall only be able to barely fulfil already accepted obligations." Perhaps some public-spirited person will offer financial aid to tide over the present difficulties.

MISTS ON MARS.—A circular from Kiel, dated December 27, reports the following information received from M. Flammarion:—"M. Flammarion announces mists (brouillards) on Mars extending to various distances round the polar cap. This whitish zone, less brilliant than the polar snow, extends to a great distance from the pole, and finally vanishes. One might easily mistake it for an extension of the polar cap itself, and this is what has occurred in old observations. M. Antoniadi has made some accurate measurements at Juvisy."

THE ATMOSPHERIC ABSORPTION OF LIGHT.

IT is well known that there are some circumstances, connected with photometric observations, calculated to make us doubt whether, theoretically or observationally, we have determined correctly the amount of light that is extinguished in its passage through our atmosphere. Foremost amongst these considerations may be mentioned the fact, pointed out some time since by Prof. Seeliger, that the very accurate and trustworthy observations made by Dr. Müller, at Potsdam, with a view to determine this quantity, are not rigorously represented by the theoretical expressions derived by Laplace. The deviations may not be large in amount, but they exhibit a systematic character which is suspicious. In the same connection may be mentioned the initial objection, urged by Prof. Langley, that the fundamental expressions used in those investigations are not equally applicable to light of all wave-lengths. There are, further, in use different numerical values of the coefficient of transmission, pointing either to various degrees of transparency in the atmosphere, or to peculiarities in the instruments themselves, or the methods employed in the reduction of the observations.

This question of the discordance between theoretical and observed results has been recently treated by Dr. Hausdorff, and greater importance has been given to the memoir by a review from Dr. Kempf, in a recently-issued *Vierteljahrsschrift*; and this last, while traversing some of the views of the authors, is, on the whole, as satisfactory and reassuring as the views of Prof. Langley and Dr. Seeliger have been disturbing. Dr. Hausdorff, concerned to reconcile theory and observation, examines in the first place Laplace's theory with great accuracy to trace whether the deviations are due to any incompleteness in the theory itself. The principal result of this inquiry is to add a term of rather complex character to the simple formula to which Laplace reduced his expression for atmospheric absorption, but which avails nothing, either in actual practice or in offering a solution of the original difficulty. The new coefficients might be of use if their physical interpretation added anything to our knowledge of the atmosphere; but whether this be assumed of infinite or limited extent, the whole effect of the new introductions, even in small altitudes, can be represented by an alteration in the constant. How little improvement, if any, the consideration of terms of a higher order has had on the computed quantities, is shown by the following table, in which Müller's observed values of atmospheric absorption (M.) (expressed in logarithms) are compared with those of Hausdorff (H.), and the more simple expressions of Laplace (L.).

Z.D.	(M.)	(H.)	(L.)	(M.)-(H.)	(M.)-(L.)
0	0·000	0·000	0·000	0	0
20	0·004	·005	·005	− 1	− 1
40	0·024	·023	·024	+ 1	0
60	0·092	·076	·077	+16	+15
70	0·180	·146	·147	+34	+33
75	0·261	·215	·216	+46	+45
80	0·394	·350	·352	+44	+42
82	0·477	·447	·448	+30	+29
84	0·607	·597	·598	+10	+ 9
86	0·846	·856	·855	− 10	− 9
87·5	1·176	1·209	1·200	− 33	− 24

Practically identical figures result whether the atmosphere be supposed infinite or of limited extent.

The essential service that Dr. Hausdorff has rendered is to show that any considerable improvement in Laplace's theory is not probable. Dr. Kempf now renders a still greater service by showing that any improvement is not needed. He raises the question whether these observed discrepancies are not rather due to observation, and removable by more appropriate methods of discussing the observation. Dr. Kempf remarks that the only observations available for examination are those of Dr. Müller, whether made at Potsdam or on the Santis. Seidel is brushed aside with a scanty reference. Pickering and Pritchard do not get even this recognition. It would probably be objected to the latter that he had not observed below 75° Z.D., and it is only after this altitude is passed, that the deviations between observation and theory become of noticeable amount. But Prof. Pickering's observations of circumpolar stars at upper and lower culminations seem to be available, and should not be rejected without reason or excuse. But it may be urged that the real object of the inquiry is to explain Dr. Müller's observations, and from the connection that has long existed between Drs. Kempf and Müller, the remarks of the former become the more valuable, since it may be assumed that Dr. Müller is cognisant of the treatment that his observations have received at the hands of his coadjutor, and has tacitly acquiesced in the process.

Dr. Hausdorff has declined to use the Santis observations, because the corrections for light extinction are founded on Laplace's theory; but Dr. Kempf shows how the observations can easily be made to furnish results independent of any theory, and consequently the discrepancies between the observations and Laplace's values can be easily exhibited. Expressed as light ratios in logs., the unit corresponding to the third place of decimals, the differences Müller-Laplace are shown in the following little table, in which no regular systematic progress is noticeable.

Z.D.	(M.-L.)	Z.D.	(M.-L.)
18°6	− 10	62°8	− 10
29°3	+ 6	72°4	+ 9
37°2	− 5	79°5	+ 3
44°6	0	82°9	+ 6
57°6	+ 3	85 8	− 7

Not only are the differences small, but in no case do they exceed twice the probable error derived from the discussion of the observations themselves. Encouraged by this satisfactory agreement, Dr. Kempf applies himself to the Potsdam results, and recalls the fact that the extinction table, on which Dr. Hausdorff so much depends, is really the result of the combination of two separate processes of observation. The first part extends from the zenith to an altitude of 10°, and has been derived by comparing the light of Polaris with that of five different stars at every possible Z.D. between 0° and 80°. For greater Z.D., however, another series has been obtained by observing, on very clear nights, the differences of lustre of objects at their rising or setting up to some 10° of altitude, and deriving from the differences the amount of absorption at the various Z D.s. Such a break in the continuity is perhaps regretable, but to some extent unavoidable. Stars that are visible in the horizon do not reach the zenith of Potsdam within some 15°, and, of course, stars culminating near the zenith do not approach near enough to the horizon. Comparing each part of Müller's general extinction table with Laplace's theory, Dr. Kempf obtains the following result (M.-L.) I.; but, for very sufficient reasons, on discarding the last observation at 80° Z.D., which is evidently discordant, and affects the accuracy of the determination of the general coefficient of transmission, he obtains the second series marked (M.-L.) II., in which the agreement leaves very little to be desired.

Z.D.	(M.-L.) I.	(M.-L.) II.	Z.D.	(M.-L.) I.	(M.-L.) II.
20°	− 2	− 2	72°5	+ 10	+ 5
40	− 3	− 4	75	+ 9	+ 2
50	− 2	− 3	77·5	+ 1	− 7
60	+ 3	0	80	− 17	—
70	+ 9	+ 5			

Nearly as satisfactory is the comparison of the theory with the second part of the table, that below 80° Z.D. The greatest deviations, when expressed in magnitude, do not exceed 0·025 m., and any one acquainted with the difficulties attending photometric observations so close to the horizon, will rather be surprised that the agreement is so close, than tempted to cavil over the small discordances. In the first part, the coefficient of transmission is 0·81; in the second, 0·85: the two parts, therefore, correspond to different degrees of atmospheric transparency, and they cannot be represented by one and the same curve. The explanation offered by Dr. Kempf will probably command a general assent, and it will be admitted that he has made out his case, that Laplace's theory of absorption corresponds exactly to the actual conditions within the limits of accuracy at present attainable.

If Dr. Kempf has provided the true explanation, it is of little use to follow Dr. Hausdorff in his further investigations, based as they are on the entire conviction that Müller's extinction table is exact, and that the discordance between theory and observation is real. His attempts to devise new formulæ on various hypotheses are not very satisfactory, simply regarded as interpolation results; and his failure to represent Dr. Müller's figures more closely, tends to confirm the probability of Dr. Kempf's suggestion. Of course, by the extension of formulæ to an inconvenient length, and the introduction of a sufficiently large number of unknowns, derived from the observations themselves, a close agreement can be forced; but even then one may be driven to such inconvenient consequences as that the intensity of light at approximately the sea-level is greater than that at the top of a mountain 2500 m. high. On no supposition (and in some instances the ingenuity displayed in the construction of hypotheses is considerable) can a formula be found that more closely represents observation than does Laplace's; and though the author did not propose to himself to establish this fact, he has rendered no slight service to theoretical photometry by the practical confirmation his work affords.

W. E. PLUMMER.

ON CERTAIN VESTIGIAL CHARACTERS IN MAN.

SEEING that Prof. Huxley, with his well-known candour, felt constrained to admit that the study of rudimentary or vestigial characters had done more than that of any other class of facts to produce general acceptance of the doctrine of evolution, and that at the same time he acknowledged the double-edged

nature of these characters, it is not out of place to appraise the evidential value of certain of them.

The direction of the hair-slope on three regions of the body, as bearing upon the simian ancestry of man, will be first considered.

(1) On the upper extremity of man the direction of the hair-slope, which may for the sake of brevity be called the *Human Type*, is as follows:—On the upper arm the slope is all downwards to the elbow, with a slightly oblique direction on the anterior surface. This direction appears to be the same as that in all the monkeys examined.

But on the fore-arm the *Human Type* is as follows:—On the flexor surface the stream of hair divides and passes obliquely to the radial and ulnar borders respectively, and to the carpus. On the extensor surface the slope continues on the radial side in a direction at right angles to the long axis of the limb, and gradually curls backwards over the posterior surface of the ulna, joining a corresponding "backwash" of the stream of hair from the ulnar border. Thus, on a small area amounting to about a fourth of the extensor surface, the united stream of hair passes directly to the elbow.

This description is based upon the examination of numerous fore-arms, hairy and non-hairy; of infants a few days old and three months old, of children from seven to fourteen years old, of adults male and female—among the adults five very hairy male subjects. In all of these fore-arms, as far as the scanty hair on some would allow one to observe it, there was very little departure from the *Human Type* as described. In the cases of infants, the hairs were very minute and required a lens to reveal them. The direction stated is easy to verify or to disprove; but it is surprising to find such a statement as occurs in "Darwin and after Darwin," by the late Prof. Romanes, where, on page 89, he says, "again, in all men the rudimentary hair on the upper and lower arm is directed towards the elbow—a peculiarity which occurs nowhere else in the animal kingdom, with the exception of the anthropoid apes and a few American monkeys. . . ." With this statement Prof. Romanes and Prof. Drummond seem to have remained satisfied, though their own fore-arms, and those of every person they might have examined, would have told a different tale, either with or without the assistance of a lens. The statement of Prof. Romanes clearly refers to the permanent hair of the body, as shown by his illustrations, and not to the lanugo or temporary hair.

The direction of the hair-slope on the fore-arm of the anthropoid apes—*the Anthropoid Ape Type*—is certainly what is stated by Romanes and Drummond, viz. towards the elbow with a slightly lateral direction both on the flexor and extensor surfaces, except in the orang, in which the slope is all directly to the elbow. This is to be seen in all the anthropoid apes at the Zoological Society's Gardens, London, in the case of the gorilla, chimpanzee, and gibbon hoolock, and in the case of the orang at the Natural History Museum, South Kensington, where also the slope of the hair on the fore-arms of gorilla, chimpanzee, and gibbon is confirmed. St. George Mivart[1] mentions one species of gibbon, *Hylobates agilis*, where the *Human Type* appears to be exceeded in the *wrist-ward* direction. He says, "in *Hylobates agilis* all the hair of both these limb-segments is directed towards the wrist."

This statement is not fully borne out by the examination of the specimens of *Hylobates agilis* at South Kensington.

In addition to these four genera of anthropoid apes, twenty-two other species of monkeys were examined as to the slope of the hair on the fore-arm, with the following results:—

A 19. *Catarhine or Old World monkeys*, as follows:—

13. Human Type, viz.:—
Cercocebus æthiops—Barbary ape—Japanese ape—Cercopithecus campbelli—Cercopithecus ruber—Cercopithecus diana—Cercopithecus callitrichus—Cercopithecus lalandii—Cercopithecus grisco-viridis—Cynocephalus anubis—Macacus maurus—Arabian baboon—Cercopithecus abigulosus.

(1) Anthropoid Ape Type, viz.:—
Cercopithecus cephus.

(5) Partial Human Type inclining to Anthropoid Ape Type, viz.:—
Cynopithecus niger—Cercocebus fuliginosus—Macacus cynomologus—Macacus rhesus—Macacus sinicus.

[1] Encyclop. Brit., vol. ii. p. 157.

B (3) *Platyrhine or New World monkeys.*

(2) Human Type, viz.:—
Cebus fatuellus—Cebus monachus.

(1) Anthropoid Ape Type, viz.:—
Ateles geoffroyi.

Thus of twenty-two lower monkeys, Old World and New World, fifteen very closely resemble the human subject in this small morphological character, whereas all the anthropoid apes (one species of one genus excepted) are markedly different from the *Human Type*.

Such things ought not to be on the theory of the descent of man from the ape. They may not alone support the opposing theory, but they ought never to have found their way into valuable and popular books, being selected from a great array of so-called vestigial characters with a view to supporting the above theory.

(2) There is no reason why the direction of the hair-slope on the fore-arm should be studied in its vestigial character, any more than that on the *thigh*. On the *thigh* the *Human Type* is as follows: On the flexor surface the hair slopes in two streams to the outer and inner borders respectively, and towards the knee. At the upper third and outer side the slope takes a direction at right angles to the long axis. On the extensor surface the streams of hair which come from the borders coalesce and pass to the back of the knee. The Simian Type is oblique, and *to the pelvis, i.e.* in the favourite position of the monkey, when sitting on its haunches, the hair falls quite vertically downwards. This statement is based on the observation of the four anthropoid apes and twenty-seven other lower monkeys, including the twenty-two previously specified, thirty-one in all. There were found, out of these thirty-one specimens, ten partial exceptions, five American monkeys, and five lower Old World monkeys, such as baboons, Barbary ape, and Japanese ape. In these ten there was a slight resemblance to the *Human Type*, but not a vestige of resemblance in one of the anthropoid apes examined.

(3) A third region of the human body shows the divergence between the *Human Type* of hair-slope and the *Simian Type* even more strongly. On the dorsal surface of the trunk in man, in the erect posture, the hair slopes in the supra-scapular region inwards and at a right angle to the middle line, on approaching which it curls downwards. Below the spine of the scapula the same direction obtains until about the level of the angle, when the hair slopes *upwards* and inwards to a point over the transverse processes of the vertebræ, where it becomes horizontal and then curls sharply downwards, joins the stream of hair from the opposite side, and passes vertically downwards in the hollow over the vertebral spines. This Human Type I have found constant in children and adults, and it differs strikingly from that of all the apes and monkeys examined, in which, without exception, the hair slopes as nearly as possible vertically downwards, when the animal is sitting.

These remarks, calculated to disparage the value of the direction of the hair-slope on the human body as a "vestige" of his descent from the ape, may be met in two ways at least. In the first place, one may be reminded that it is not to the few existing anthropoid apes, "living fossils," indeed, but to some unknown *dead* fossil apes of the Miocene period that we must look for the direct ancestry of man, and that the difference in the hair-slope pointed out is consequently unimportant. Perhaps it is. But the supposed resemblance was thought worthy of prominence in the works of evolutionists, and accordingly the ascertained divergence is worthy of not less prominence.

In the second place, the differing hair-slope on the *fore-arm*, *thigh*, and *back* of man and the anthropoid apes, may be explained by the possible influence which the greater weight of the long hair covering the bodies of apes would have in producing a *generally vertical direction* of hair-slope in the sitting posture. This posture doubtless is the one in which far the greater part of the life of the ape is spent, and a little consideration of the position of an ape in sitting, will show that gravitation would tend in the case of long-haired apes to produce the *Anthropoid Ape Type* on the fore-arm, thigh, and back. In the case of man, the action of gravity would be unable to influence the slope of his short rudimentary hairs. This suggestion of a possible cause contributing to the hair-slope on the bodies of apes has, however, no bearing on the question of fact. It may be an explanation, but the facts remain.

Thus man in these characters resembles much more closely the lower Cercopithecidæ and Cebidæ than his supposed

nearest congeners, at present existing. It is also incorrect to assert that only in man, a few American monkeys, and the anthropoid apes, does the hair slope towards the elbow. This Human Type is seen in the corresponding area of this segment of the anterior extremity of almost all hairy mammals, excepting most of the Ungulate types, and those with woolly hair. It is found very constantly in Carnivores, especially those which frequently rest in a "couchant" attitude, in which the head is held erect, the fore-limbs planted in front of the body, and the extensor surface of this limb-segment resting flat on the ground, also in certain other positions of rest; and it can be seen in nearly all wild Carnivores and domestic cats and dogs. In those Carnivores which assume this attitude the posterior limbs adopt a much more variable "pose," and here there is no constant form of hair-slope. The backward curl of hair on this narrow area of the fore-arm in man, certain monkeys, and many other hairy mammals, seems to be due to a mechanical force, slowly acting downwards and forwards, which makes for this direction of hair-slope. In all these three classes it is obvious that such pressure is frequent. This explanation of an inherited character, maintained by a simple physical cause, meets the case far better, I submit, than any supposed tracing out of ancestral vestiges. WALTER KIDD.

IS ANIMAL LIFE POSSIBLE IN THE ABSENCE OF BACTERIA?

SOME ten years ago Pasteur, in one of those "causeries du laboratoire" which those who were privileged to take part in will never forget, discussed with the young scientific men around him the interest which would attach to the nourishment of an animal from its earliest existence with sterilised food under conditions which would ensure the absence of all microbial life. "Sans vouloir rien affirmer," he added, "je ne cache pas que j'entreprendrais cette étude, si j'en avais le temps, avec la pensée préconçue que la vie dans ses conditions deviendrait impossible. . . . Que le résultat soit positif et confirme la vue préconçue que je mets en avant ou qu'il soit négatif et même en sens inverse, c'est-à-dire que la vie soit plus facile et plus active, il y aurait un grand intérêt à tenter l'expérience."

To decide this question Messrs. George Nuttall and H. Thierfelder have carried out elaborate experiments in the Hygienic Institute of the Berlin University with young guinea-pigs removed from the mother by means of the Cæsarean operation. Every conceivable precaution was taken to prevent all access of bacterial life. The young guinea-pig was placed in a sterilised chamber, supplied with sterilised air, and it was fed exclusively upon sterilised milk. It had to be supplied with food every hour, day and night, a process which so exhausted the investigators that at the end of eight days, when it had consumed 330 cubic centimetres of milk, and to all appearances was in perfect health and spirits, it was killed.

A microscopic examination of the contents of the alimentary canal revealed no bacteria whatever; ærobic and anærobic cultures in various media were further made of the intestinal contents and of the excreta, but in every case the culture tubes remained sterile, not a single colony made its appearance. Messrs. Nuttall and Thierfelder claim by these experiments to have proved conclusively that the presence of bacteria in the alimentary canal is not essential to vital processes, at any rate in the case of guinea-pigs; and they consider themselves justified in assuming that other animals, and also human beings, could similarly exist in the absence of bacterial life, as long as the food supplied is purely animal in character. Whether the conditions would be altered by the addition of *vegetable* food to the diet, they next endeavoured to determine. In this series of experiments the food selected was so-called "English" biscuits containing about 7 per cent. nitrogenous material, 9 per cent. fat, 17 per cent. sugar, 58 per cent. of other non-nitrogenous matters, and 0·2 per cent. cellulose; these, together with the milk employed, were sterilised before use. The same rigorous precautions characterised these experiments as the previous ones; more animals were, however, secured, and they were allowed to live longer. The weight of the animals was this time carefully noted, and during the ten days, during which the experiment lasted, one animal gained 23 grammes and another 11 grammes. This calculation could only be an approximate one, as the experimental animals were not weighed when originally removed from the mother, and their initial weight was only arrived at by weighing the other guinea-pigs which were removed at the same time, but not experimented upon. Thus in the case of vegetable substances bacterial life is apparently also not essential for carrying on digestive processes. The authors made also as careful an examination as was possible with the limited amount of material at their disposal, of the urine, and state that aromatic oxyacids were undoubtedly present. This result they regard as confirmatory of E. Baumann's assertion that aromatic oxyacids may be elaborated independently of intestinal decomposition. To this point they intend, however, to return later; at present further investigations are in progress with fowls, and the results will be awaited with the greatest interest, while immense credit is due to the authors for the ingenuity of the methods they have devised, and the self-sacrificing laboriousness with which they have conducted the experiments.

SOCIETIES AND ACADEMIES.

EDINBURGH.

Royal Society, Dec. 21, 1896.—Lord Kelvin in the chair.—The first paper, on atomic configurations in molecules of gases according to Boscovich, was by the President himself. At the outset Lord Kelvin confessed that the problem was quite beyond him, and he only desired to throw out some suggestions. Boscovich's theory would quite well explain the atomic configuration of a gas if we could only apply it. In a monatomic gas the problem was fairly easy, collision between molecules leading to change in direction, either backwards on the original path, or at an angle, according as the impact was direct or oblique. For a diatomic gas we must imagine a "pair of somethings" held together by a mutual force which knocked about like one. He thought he could see why a diatomic gas should become monatomic when its temperature was sufficiently raised. But he could not yet understand why, when the process was reversed, molecules should combine in quartettes rather than in pairs, or triplets, and he illustrated his conjectures by means of models. He showed by means of these how, for example, the mutual repulsion between the H's might prevent O from combining with any more than two, and hence we did not have H_2O. And he explained, similarly, how O_3 was unstable, as the octohedral arrangement of the atoms (taking $O = O_3$) was easily broken up. But the whole subject was one of tremendous difficulty.—In an abstract from a paper on the cæcal fossæ, Dr. Richard Berry pointed out that the pericæcal folds and the resulting fossæ were primary in origin, and vascular in evolution. He strongly dissented from Treves' view that the meso-appendix is a substituted mesentery, maintaining that the ilio-colic and ilio-cæcal folds were the true cæcal mesenteries, primary and subsidiary respectively, the meso-appendix being the true appendicular mesentery. Arguing from this and other facts which he adduced, Dr. Berry stated that it would almost appear as though the appendix were gradually replacing the cæcum in functional activity. Passing on to the retro-cæcal fossæ, he pointed out the inaccuracy of the term retro-cæcal as applied to these fossæ, suggesting for them the name retro-colic as being more accurate and more scientific. He proceeded to show that these fossæ were secondary in origin and depended for that origin upon the secondary coalescence, sometimes wanting, of the colon, cæcum, and mesentery, to the posterior abdominal wall. In this respect Dr. Berry differed from almost every British author. He pointed out the variability of these fossæ in number and position, and strongly emphasised their importance to the surgeon in view of the prevalence of appendicitis and the part which these fossæ, according to the author, play in the etiology of that disease.—Dr. T. H. Milroy read a paper dealing with research into the nature of the nucleins and paranucleins of the animal cell. During the last few years much attention has been paid to two great classes of proteids intimately connected with the life of the cell, viz. the nucleins and paranucleins. The former class has been rather vaguely defined as including proteids which have only two points in common—a high percentage of phosphorus in organic combination, and a marked resistance to the action of the gastric secretion. The natural nucleins examined were those of the thymus gland of calves, of the red blood-corpuscles of birds, and of the pancreas of the ox; and these were found to agree in almost every particular with artificial syntonin-nuclein. That is, they were only slowly dissolved, not decomposed by the gastric juice (with the exception of the pancreas nuclein), while trypsin and sodium

carbonate rapidly split them up, the phosphorus passing into solution in organic combination. This phosphorus-holding body is acid in nature, and possesses marked proteid-precipitating properties. It does not seem to be either nucleic or meta-phosphoric acid. It was not present in the products obtained from tryptic digestion of the nucleins of the red blood-corpuscles of birds. The combination between paranucleic acid and albumin in ovovitellin is not a firm one, as the acid is easily obtained by the action of weak alkaline solutions upon the mother substance. The acid so obtained is not impure nucleic acid, as Altmann thought, because no nuclein bases appear among its decomposition products. It is very soluble even in cold water, and the solutions so obtained precipitate albumins, &c., out of their solutions. It gives a distinct Buiret reaction but no red colour with Milton's reagent. It does not give any precipitate with ferrocyanide of potassium and acetic acid. It contains, on an average, about 7·8 per cent. phosphorus. From the nucleic acid of the thymus another acid can easily be obtained which still retains the proteid-precipitating power of the original acid, but no longer gives, on decomposition, nuclein bases, agreeing in these particulars with the paranucleic acid of the paranucleins. These point at least to means by which the nuclein series of proteids may be built up and decomposed in the animal organism.—A paper by Dr. Thomas Muir, on the expression of any bordered skew determinant as the sum of products of Pfaffians, was taken as read.—Lord Kelvin then, by permission of the Council, gave an extra paper describing the result of experiments conducted by him along with Drs. Beattie and Smolan as to the effect of Röntgen rays on air (see p. 199).

PARIS

Academy of Sciences, December 28, 1896.—M. A. Cornu in the chair.—On the method of Bruns, by M. Poincaré. An account of an exception to Bruns' theorem, and an amendment to part of his proof.—A new theory of cicatrisation, and on the part played by the anterior epithelium of the cornea in the healing of wounds in this membrane, by M. L. Ranvier. Observations showing that cellular multiplication is not indispensable to the formation of a cicatrix, and that this multiplication, when it occurs, is of only secondary importance in the process of healing.—New note on the application of radioscopy to the diagnosis of diseases of the thorax, by M. Ch. Bouchard. Several cases of diseases of the thorax were clearly made out by the use of the Röntgen rays with fluorescent screen, but a study of diseases of the abdomen has given much less satisfactory results.—The energy consumed by a muscle in static contraction sustaining a load, studied by means of the respiratory exchanges, by MM. A. Chauveau and J. Tissot.—On the fossil hippopotami of Algeria, by M. A. Pomel. Some remarks on a monograph submitted by the author on the quaternary fossil hippopotami of Algeria.—New nebulæ, discovered at the Observatory of Paris, by M. G. Bigourdan. The positions are given of nebulæ numbered 245 to 281.—On the transformations of differential systems, by M. Etienne Delassus.—On a series relating to the theory of linear differential equations with periodic coefficients, by M. A. Liapounoff.—On the movement of a solid in an indefinite liquid, by M. W. Stekloff.—On the use of a system of numbered points in the representation of equations, by M. M. d'Ocagne.—On a thermic machine, by M. Delsol. An account of the theory of a machine designed to utilise the work done by the gas given off on heating a solution of ammonia.—On the problem of vibrating membranes, by M. Le Roy.—Methods of calculation in electromagnetism, by M. Vaschy.—Effect of the state of the polar surfaces of an exciter on the explosive potentials, static and dynamic, by M. Swyngedauw.—Action of the X-rays on gaseous dielectrics, by M. L. Benoist. It is shown that the law recently found experimentally by M. Jean Perrin, is really identical with that previously enunciated by MM. Benoist and Hurmuzescu.—New facts in the application of radioscopy to intrathoracic lesions, by M. J. Bergonié. The outline of the shadow cast by tubercular lesions was traced out in pencil on the body, with the aid of the fluorescent screen. The line thus drawn was found to coincide with remarkable precision with that previously marked out after a careful study by auscultation and percussion.—On a Crookes' tube for use with alternating current dynamos, by MM. Oudin and Barthélemy.—The Hall-phenomenon in liquids, by M. H. Bagard. A reply to the criticism of M. Floris.—Action of lithium upon carbon and some carbon compounds, by M. Guntz. When lithium, contained in a carbon boat, is heated in nitrogen gas, the boat is attacked, lithium carbide and cyanide being formed. Lithium carbide alone is produced if the heating is performed in a vacuum. The same substance is found among the products of the action of CO and CO_2 upon heated lithium. At 700°, ethylene is completely absorbed by the metal, with the formation of a mixture of lithium carbide and hydride. Acetylene behaves similarly. Methane is only very slightly attacked by lithium at a red heat.—On cyanuric chloride, by M. Paul Lemoult. A thermo-chemical study of the chloride $C_3N_3Cl_3$.—Action of carbonic acid of waters on iron, by M. P. Petit.—The action exerted on solutions of haloid alkaline salts by the corresponding haloid acid, by M. A. Ditte.—On the action of phosphorus on platinum, by M. A. Granger. At very high temperatures, the phosphide obtained appears to be Pt_2P, at lower temperatures using platinum black a phosphide is obtained from which aqua regia extracts Pt_3P_5.—Action of hydrogen chloride in the gaseous state upon alkaline sulphates, by M. Albert Colson.—The reduction of wolfram by carbon in the electric furnace, by M. Ed. Defacqz. The metal produced contained 92·5 per cent. of tungsten, 50 per cent. of carbon, and traces of iron and other metals.—New examples of normal rotatory dispersion, by MM. Ph. A. Guye and P. A. Melikian.—On the transformation of the sulphonated camphophenols into dinitro-orthocresol, by M. P. Cazeneuve.—On hexadiinediol, by M. R. Lespieau. Propargyl alcohol is converted into its cuprous compound by shaking with ammoniacal cuprous chloride, and this oxidised with potassium ferricyanide gives the alcohol, $CH_2.OH-C\equiv C-C\equiv C-CH_2.OH$.—Contribution to the study of borneols and their ethers, by M. J. Minguin.—The freezing point of milk; reply to a note by MM. Bordas and Génin, by M. J. Winter.—Optical analysis of urine and the exact estimation of the proteids, glucosides, and non-fermentable saccharoid substances, by M. Frédéric Landolph.—General observations on wheat, by M. Balland.—Immunising properties of the serum of the eel against snake venom, by M. C. Phisalix.—On the morphology of *Cryptococcus guttulatus*, by MM. J. Kunstler and P. Busquet.—The regeneration of the vesical epithelium, by M. Etienne de Rouville.—On the presence of an oxydase in the branchia, palps, and blood of the Acephala, by MM. Pieri and Portier.—Parasitism and evolution of two Monstrillidæ in the interior of the vascular system of the Filigranæ and Salmacynæ, by M. A. Malaquin.—New mosasauria found in France, by M. Armand Thévenin. The fossil described was found in the grey phosphatic chalk beds in the north of France, and appears to be the skull of a reptile closely allied to *Mosasaurus giganteus* (Moestricht). The teeth, however, show differences, and the name *Mosasaurus Gaudryi* is given to the species. Another skull found appears to be allied to the American species *Platecarpus*, and the name *Platecarpus Somenensis* is proposed for it.—On the structure of the fundamental protoplasm in a species of *Mortierella*, by M. L. Matruchot.—A new micrococcus of the potato, by M. E. Roze.—Synthesis of hauksite, by M. A. de Schulten. The hexagonal crystals of $4Na_2SO_4.Na_2CO_3$, obtained by pouring a hot solution of sodium sulphate and carbonate into a strong solution of caustic soda, possess the composition and properties of natural hauksite.—Observations on some asphaltic rocks and on the origin of asphalte, by M. Stanislas Meunier. The conclusion is drawn from the behaviour of bituminous rocks towards solvents, that bitumen is the result of purely mineral reactions, of the type of the double decomposition between metallic carbides and water.—On the identity of the phosphates from the Paris and London basins, and on the Tertiary age of this deposit, by M. N. de Mercey.—Documents serving for the geological study of the neighbourhood of Luang Prabang (Cochin China), by M. Counillon.—On the Foiba of Pisino (Istria), by M. E. A. Martel.

NEW SOUTH WALES.

Linnean Society, November 25, 1896.—The President, Mr. Henry Deane, in the chair.—On the comparative anatomy of the organ of Jacobson in Marsupials, by Dr. R. Broom.—Observations on the eucalypts of New South Wales, Part ii., by Henry Deane and J. H. Maiden.—On a new species of *Macadamia*: together with notes on two plants new to the colony, by J. H. Maiden and E. Betche. (*a*) *Macadamia integrifolia*, n.sp., is a small tree originally found near Camden Haven, N.S.W., now under cultivation in the Botanic Gardens, Sydney. It is very closely allied to the well-known Queensland nut, *M. ternifolia* (also found in N.S.W.), from which it may be readily distinguished by the petiolate entire leaves, rather smaller fruits,

and less hairy flowers and inflorescence. (*b*) *Cheirostylis grandiflorus*, Blume, found "in moist forests between rocks on the coast of New Guinea," is now recorded from similar situations near Lismore, Richmond River, N.S.W. Its discovery adds a genus to the flora of Australia. (*c*) *Grevillea alpina*, Lindl., hitherto only recorded from Victoria, has been found in the Albury district.—On a new fungus (*Capnodium callitris*) attacking the Murray pine; together with observations on a fungus found on *Hypocheris radicata*, L., by D. McAlpine.—On some Australian gudgeons (*Eleotridinæ*), by J. Douglas Ogilby.—Descriptions of some new *Araneidæ* of New South Wales. No. 7, by W. J. Rainbow.—Contributions to a knowledge of the arachnidan fauna of Australia, No. 1, by W. J. Rainbow. This paper, the first of a new series, is descriptive of a new scorpion (*Buthus flavicruris*) from Como, obtained by Mr. J. D. Ogilby.—On Domatia in certain Australian and other plants, by Alex. G. Hamilton.—Description of a new species of Pupina from Queensland, by C. E. Beddome.—Revision of the genus *Parapsis*, Part i., by Rev. T. Blackburn.—The Silurian trilobites of New South Wales, with references to those of other parts of Australia. Part iv. The *Odontopleuridæ*, by R. Etheridge, jun., and John Mitchell.—Note on a Papuan throwing-stick, by J. Jennings.—On the so-called evidences of glaciation on the Mt. Kosciusko plateau, by Rev. J. Milne Curran. The author concluded that (1) there is no satisfactory evidence of glaciers in the present valleys. (2) There is absolutely no evidence of extensive glaciation on the Kosciusko plateau. (3) The "glacial epoch in Australia" in Post-Tertiary times as described by Dr. Lindenfeld, has no foundation in fact.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 7.

ROYAL INSTITUTION, at 3.—Visible and Invisible Light: Prof. S. P. Thompson, F.R.S.

FRIDAY, JANUARY 8.

ROYAL ASTRONOMICAL SOCIETY, at 8.—A Method of Clearing a Lunar Distance: F. C. Penrose.—Determination of the Diameter and Compression of the Planet Mars, from Observations with the Repsold Heliometer of the Royal Observatory, Göttingen: W. Schur.—On the Comparison of Reflector and Portrait Lens Photographs: Dr. Isaac Roberts.—Note on the Magnitude of η Argûs, 1896: R. T. A. Innes.—Orbit of 44 Bootis Ba. 15 = Sh. 193 = Σ 1909: S. W. Burnham.

SATURDAY, JANUARY 9.

ROYAL INSTITUTION, at 3.—Visible and Invisible Light: Prof. S. P. Thompson, F.R.S.

SUNDAY, JANUARY 10.

SUNDAY LECTURE SOCIETY, at 4.—Artificial Light: Prof. Vivian B. Lewes.

TUESDAY, JANUARY 12.

ANTHROPOLOGICAL INSTITUTE, at 8.30.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Superheated Steam Engine Trials: Prof. W. Ripper.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Photography by the Röntgen Rays, up to date: Dr. Hall-Edwards.

WEDNESDAY, JANUARY 13

SOCIETY OF PUBLIC ANALYSTS, at 5.—Annual Meeting.—Also, some Analyses of Water from an Oyster Fishery; Note on Weighing out Fats; Remarks on Formaldehyde: Chas. E. Cassal.—A Specific Gravity Pipette: W. F. Keating Stock.—A Modified Schmidt Process: R. W. Woosnam.

THURSDAY, JANUARY 14.

MATHEMATICAL SOCIETY, at 8.—Supplementary Note on Matrices: J. Brill.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Inaugural Address of the President, Sir Henry Mance.

SOUTH LONDON ENTOMOLOGICAL AND NATURAL HISTORY SOCIETY.—Some Marine Mimics: E. Step.

FRIDAY, JANUARY 15.

EPIDEMIOLOGICAL SOCIETY, at 8.—Age Incidence in Relation with Cycles of Disease Prevalence: Dr. Hamer.

INSTITUTION OF CIVIL ENGINEERS, at 8.—On "Monier" Girders and Arches: Walter Beer.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Register of the Associates and Old Students of the Royal College of Chemistry, &c.: T. G. Chambers (Hazell).—Œuvres Scientifiques de L. Lorenz, Revues et Annotées par H. Valentiner, Tome 1, Fas. 1 (Copenhague, Lehmann).—A Handbook to the Game Birds: W. R. Ogilvie-Grant, Vol. 2 (Allen).—Microscopic Researches on the Formative Property of Glycogen: Dr. C. Creighton. Part 1. Physiological (Black).—Coloured Figures of the Eggs of British Birds, with De criptive Notices: H. Seebohm, edited by Dr. R. B. Sharpe (Sheffield, Pawson).—The Collected Mathematical Papers of Arthur Cayley, Vol. xi. (Cambridge University Press).—The Constitution and Functions of Gases, &c.: S. J. Corrigan (St. Paul, Pioneer Press Company).—Untersuchungen über Bau, Kernteilung und Bewegung der Diatomeen: R. Lauterborn (Leipzig, Engelmann).—Smithsonian Institution Report to July 1894 (Washington).—Notes of Lessons on Elementary Botany: W. Bland, 12th edition (Bemrose).—Outlines of Psychology: W. Wundt, translated by C. H. Judd (Williams and Norgate).—A Dictionary of Birds: A. Newton and others, Part 4 (Black).—Catalogue of the African Plants collected by Dr. F. Welwitsch in 1853–61. Dicotyledons, Part 1: W. P. Hiern (London, British Museum, Natural History).—Inorganic Chemical Preparations: Dr. F. H. Thorp (Boston, Ginn).—Oceanic Ichthyology: Drs. G. B. Goode and T. H. Bean, Text and Plates (Washington).—Life Histories of North American Birds: Captain C. Bendire (Washington).—A Catalogue of 16,748 Southern Stars deduced by the U.S. Naval Observatory from the Zone Observations made at Santiago de Chile (Washington).—Sixteenth Annual Report of the U.S. Geological Survey, Part 1 (Washington).—Annals of the Royal Botanic Garden, Calcutta, Vol. v. Part 2; Vol. vi. Part 1; and Vol. vii. (Calcutta, Bengal Secretariat Press).

CELLULOSE.—THE CHOICE OF PAPER FOR BOOKS.

Cellulose: an Outline of the Chemistry of the Structural Elements of Plants with reference to their Natural History and Industrial Uses. By Cross and Bevan. Pp. 320. (London: Longmans, Green, and Co., 1895.)

NO more aggravating book could be placed in the hands of a reviewer: inchoate in the highest degree, it deals with a subject of extraordinary interest and importance in an absolutely original manner; it teems with suggestions which those who can read between the lines will find of the greatest value; but it is disfigured by an obscurity of diction which must materially diminish its usefulness, and to do it justice a degree of patience and long-suffering must be exercised which probably few possess. Certainly it has taken me a long time to screw up my courage to the point of venturing to publicly discuss its merits; but the delay has served a good purpose: had I recorded my first impressions, they would have been highly unfavourable; whereas I can now say that the more often I take the book in hand the more it fascinates me, and the more I realise how important are the problems it presents for consideration. In fact, whatever the faults of the work, all who are in any way concerned with the manifold uses which cellulose subserves, whether in nature or art, must seek to appreciate its contents, and must study it as by far the most important contribution to the subject published since the appearance in 1876 of the magnificent fragment, entitled, "Die Pflanzenfaser und ihre Aufbereitung für die Technik," by Dr. Hugo Müller. A comparison of the two books shows how extraordinary is the progress made during the past twenty years; and yet how absolutely ignorant we remain of the nature of cellulose.

Many may ask, What is cellulose? To which we must reply, We cannot say! It is impossible at present to define it more exactly than as being the main element of the cellular structure of plants; as the structural basis of the vegetable world—to use Messrs. Cross and Bevan's expression, so that its German appellation, cell-stuff, gives in a single word the best definition possible. But whereas formerly we thought of it always in connection with cotton-wool, it is now becoming customary to associate the name with a variety of substances, and to regard cotton-wool cellulose as only the most highly developed term of a series of celluloses.

Cellulose belongs to the great secret society we term *carbohydrates*—I say secret, because all but the inferior members are sealed books to us. A carbohydrate is a compound in which carbon is associated with oxygen and hydrogen, these elements being present in the proportions in which they occur in water; an important consideration to be borne in mind when the attempt is made to consistently define a cellulose. For years we lived under the comfortable conviction that the carbohydrates contained, if not six, some integral multiple of six carbon atoms in the molecule, and they were all natural products; but then it was discovered that ordinary gum arabic affords a carbohydrate containing only five atoms of carbon—*i.e.* the pentose arabinose; and more recently we have learnt to improve on nature, and have shown how vastly greater are our powers by raising the number of hexaldoses isomeric with ordinary honey glucose, $C_6H_{12}O_6$, from three—the number obtained from natural sources—to eleven; the maximum number possible being, we believe, sixteen: a sufficiently wonderful achievement; in fact, probably the greatest feat recorded in the history of chemical discovery, and the more so when we consider that we have not only made them, but have also, we venture to believe, successfully allocated to the atoms in the molecule of each of the forms their relative positions in space. It may be added that we are now acquainted with a complete series of homologous "glucoses" containing from one up to nine carbon atoms, most of them being artificial products.

Nature, however, has hitherto baffled us in the case of so well-defined a carbohydrate as ordinary sugar—call it, as we may, either cane or beet sugar, since but one and the same substance is procurable from either source, although many "educated" folk still insist on the contrary. Notwithstanding that we know the size of its molecule, we have not yet precisely determined its structure, which is proof that our analytic powers are after all but very limited, and that there is no relation between cheapness and constructiveness: as if there were, we should long ago have entirely mastered a material tons upon tons of which may be had in an almost pure state at about twopence a pound—in itself a sufficiently noteworthy circumstance; indeed, no other article of commerce illustrates in so striking a manner the perfection attained in modern manufacturing processes. Above cane sugar, higher in the series, all is chaos: of dextrin, glycogen, inulin, starch and the celluloses, &c., we know no more than that in some way they are, with very few exceptions, derived from ordinary glucose; it is generally supposed that their molecules are *highly* complex, but the evidence on this point is by no means complete. Progress is barred by the absence of methods of attacking such problems, and we must patiently await the arrival of the pioneers who will successfully penetrate into regions which we have hitherto always failed in exploring beyond the frontiers. From this point of view, especially, men like Messrs. Cross and Bevan are particularly deserving of encouragement, as they have given clear proof of ability in opening up new lines of inquiry—by far the most valuable office to render at such a juncture.

Cane sugar, $C_{12}H_{22}O_{11}$, and its congeners are with great facility resolved into two hexose molecules by hydrolysis; and all other higher carbohydrates, excepting the celluloses, are without difficulty simplified by the action of dilute mineral acids and a number of enzymes. The behaviour of starch is altogether remarkable: when subjected to the action of an extract of malt, it is very rapidly attacked, even at ordinary temperatures, if previously gelatinised; in the first instance, it is converted into soluble starch, and then into "dextrins" and maltose, the isomeride of cane sugar. This is not the place to enter into any discussion of the various "dextrins," or of the peculiarities which they manifest:

suffice it to say that the subject is still enshrouded in mystery.

Although some, if not all, of the celluloses more or less readily undergo hydrolysis under natural conditions in plants, the difficulty with which cotton cellulose is resolved by acid hydrolysts is surprising in comparison with the readiness with which starch is attacked; and when hydrolysis takes place, the tendency is to form dextrose: in no case has the production of a substance corresponding to that of maltose from starch been observed. How are these and other peculiarities to be explained? At present the only thing clear to us is that although fundamentally both dextrose derivatives, cellulose and starch are seemingly constructed on different types; so that the conversion of one into the other, in whichever direction it may occur, involves a passage through dextrose.

Messrs. Cross and Bevan attach great importance to the formation from cellulose of a large quantity—30 to 35 per cent.—of acetic acid on fusing it with alkali, a behaviour which no other carbohydrate exhibits; to account for this, they assume that cellulose contains the group $CO.CH_2$, and they are inclined to think that this forms part of a closed chain of six carbon atoms constituting the fundamental C_6 group of the carbohydrate; but in the absence of definite evidence, so unconventional a view can only be regarded as a working hypothesis put forward with the object of emphasising the peculiarities of cellulose in comparison with other carbohydrates.

There are, at least, two other types of cellulose which are far more widely distributed in the plant world than is that of the cotton type, viz. those obtained from woods and ligneous tissues generally, and those from cereal straws, esparto, &c.; but such celluloses contain a larger proportion of oxygen, and are in fact *oxycelluloses*—so that, strictly speaking, they are not carbohydrates: they are characterised by yielding more or less furfuraldehyde on distillation with muriatic acid, wood cellulose giving from two to six per cent., and esparto as much as twelve. The ligno-celluloses constitute another class, belonging, however, to the group of compound celluloses, of which there seem to be many varieties; they contain a non-cellulose constituent almost of a benzenoid character. All these are much less resistant than cotton cellulose. In a recent communication to the Chemical Society Messrs. Cross, Bevan, and Smith have shown that it is possible, by a process of regulated hydrolysis, to resolve the cereal straws into a resistant cellulose and a substance which they believe to be a formal-pentose, $C_5H_8O_3\begin{smallmatrix}O\\ \diagup\\ \diagdown\\ O\end{smallmatrix}\!\!>CH_2$; they regard this as the primary source of the furfural obtained on hydrolysing many celluloses. Furthermore, they find that the substance of this type varies in character with the stage of growth, being completely fermentable at an early stage, but not in the later stages. This discovery marks an important advance in our knowledge, and its development may be looked forward to with the greatest interest.

Finally, it is to be noted that in addition to celluloses primarily derived from ordinary dextrose, others exist in the formation of which isomerides of dextrose have taken part—vegetable ivory, for example, yields instead of dextrose the closely related substance mannose on hydrolysis, mannose differing from dextrose only in the relatively different position of the groups associated with the asymmetric carbon atom next the COH group.

These illustrations will suffice to show how complex a chapter in organic chemistry we have to deal with in considering the celluloses; but it is only in recent times, and in no small measure owing to Messrs. Cross and Bevan's work, that we have been led to appreciate this fact. A perusal of their book will show how, as yet, we have but touched the outermost fringe of the inquiry into their nature, metamorphoses and origin, and how fertile, but at the same time infinitely difficult, a field they present for research.

It is almost impossible to exaggerate the value of a thorough knowledge of all that relates to the celluloses, when we consider the astonishing variety of uses to which they are put, and the importance of the industries in which they constitute the raw material. Thus we not only clothe ourselves largely with cellulose in the form of cotton and linen fabrics, and make from it the paper on which we write and on which we print our books, besides using it for a multitude of other peaceful purposes, but even convert it into guncotton, and from this fashion smokeless powder wherewith to confound our enemies: indeed, no more striking illustration of the revolution in our practices that science is effecting could be given than is afforded by the fact that a material like gunpowder, after being in use during so many centuries, should have been suddenly, almost entirely, displaced by the cellulose nitrates and the closely related nitro-glycerin—the glycerin, from which the latter is made, also being obtained largely from vegetable sources as well as from animal fats, and being procurable as a bye-product, in large quantity, because our modern civilisation has imposed upon us the fashion of constantly washing with the aid of soap, which we are impelled to buy by ubiquitous advertisements.

Now that the plastic nature of the celluloses is becoming understood, it is to be expected that they will be made use of in many other equally striking novel ways: the projected manufacture of a substitute for silk through the agency of nitrated cellulose is a case in point.

Messrs. Cross and Bevan have much to say on the quality of paper on which permanent records should be printed—undoubtedly a question of great importance, which has in no way received the attention it deserves. Their book is printed upon a paper carefully selected as composed of "normal" celluloses, to the exclusion of the inferior celluloses ordinarily employed in the manufacture of printing papers; and it certainly affords an agreeable contrast in this respect to the majority of books issued at the present day. Formerly, when paper was made of rags, and china clay was used with a very sparing hand, the material was both strong and little liable to undergo deterioration under ordinary influences—*mais nous avons changé tout cela*. Nowadays not only is a prodigal use made of china clay, but the place of rags is very largely taken by wood and straw. As already pointed out, the celluloses derived from such sources are far less resistant than cotton cellulose; in fact, all papers made from such materials are liable to suffer discolouration under the

ordinary conditions of wear and tear, and as they undergo oxidation somewhat readily, they gradually perish and become rotten. Yet, as Messrs. Cross and Bevan point out, in the case of papers used for writing and printing, permanence is a first desideratum :—

"Books and records have more than a passing value, and it is essential that they should be committed to pages suitably resistant both to chemical and mechanical wear and tear . . . *there is no public opinion in this country upon this important subject.* Where preferences for high-class papers exist, they are based rather upon æsthetic and other recondite considerations than upon any judgment as to composition and the relation of their constituents to the destructive agencies of the natural world. On this basis, while papers admit of a very simple classification into three main groups : (A) Those composed of the normal and resistant celluloses only—*e.g.* cotton, linen ; (B) those composed of celluloses containing oxidised groups or oxycelluloses—*e.g.* wood-cellulose, esparto and straw celluloses ; (C) those containing, in admixture with the above, ground wood or mechanical wood pulps (ligno-cellulose) . . . Class A stands beyond criticism. . . . fibres of Class B have been introduced in response to the enormously increased consumption of paper in this century. . . . their use in books is open to the very obvious objection that the books are more perishable. Of course, it is perfectly true that a large amount of literature is of the ephemeral kind, and in this province such questions as we have raised do not enter ; on the contrary, paper being very much cheapened by the use of these celluloses, a great advantage is gained. It must be insisted upon, however, that authors and publishers should have a definite judgment as to the papers to which they commit their productions, and it would be of the greatest utility to exhaustively investigate these particular celluloses from the point of view of their resistance to the natural processes of decay. Class C : The presence of ligno-cellulose is a more extreme departure from the sound basis of composition represented by Class A . . . papers of this class are only permissible where lasting properties are a question of no moment whatever. . . . The practice of loading papers with china clay . . . is also another of the causes which lead to disintegration of modern papers as compared with those of former days. There is, of course, the other side to this question, the addition of these mineral diluents having certain positive advantages not to be overlooked. The danger of any practices of this kind only enters when they are not measured at their proper utility. *Paper is largely taken for granted by consumers.* In a great many, perhaps the majority of cases, this uninquiring consumption is not attended with any serious consequences ; but, on the other hand, it is quite obvious that it is attended with dangers of a very grave character, when we are dealing with records of value for all time. This, of course, is largely a question for posterity, to whom we are handing down a literature produced upon grounds for the most part of mere commercial expediency. *It is high time, as we have said before, that a public opinion should be formed upon this subject,* and it can only be formed upon a recognised classification of papers, based upon the mechanical and chemical constants, which are determinable by laboratory investigation." (The italics are introduced by me.)

But there is a sunny side to Messrs. Cross and Bevan's disclosures, as they appear to offer a method of overcoming some of the difficulties introduced by the plethora of publications with which we are overwhelmed at the present day, and foreshadow a course of action by which readers of scientific papers might be greatly helped. If we remember that cotton cellulose is unaffected by aniline salts, which colour the oxycelluloses yellow to red, we can imagine what the result might be if all books worth preserving, and just those parts of our scientific papers which are really worth consideration, were printed on sound rag paper. On receipt of a journal, a light wash of aniline solution might be applied to each page : soon afterwards a rosy blush would pervade the greater number, only a few here and there, or those just at the beginning or the end of a paper, retaining their virgin purity of tone : we should at once know what was padding, copied from the note-book to produce an impression of much labour expended and of deep learning ! Works could be avoided by budding authors who in the process of self-education had given birth to compilations to "satisfy wants" felt by themselves alone, and the choice of students restricted to trustworthy sources of information. And the joy of the reviewer would also be great, as he could ascertain what value author and publisher placed on a book, especially if a standard series of tints, corresponding to the several varieties of paper, had been agreed to ; moreover, it would not be necessary to read reviews, and advertisements could be curtailed—as the words "Printed on Class A paper" would serve as a recommendation far better than any garbled "Opinions of the Press." I do not propose to protect the idea, but offer it freely to our Royal and other Societies, although I am aware that a patent is said to be a good advertisement, and the best means of enforcing use. Indeed, I trust that, in making the suggestion, I am but showing that I have derived profit from Messrs. Cross and Bevan's invaluable book, which is most properly printed on Class A paper.

As they truly remark at the close of their work, the chemistry of cellulose

"is a province of applied chemistry where, as in many others, the distinctions between 'science' and 'practice' exist only in the minds of those who grasp neither the one nor the other. Manufacturers and technical men, if they will only take the trouble to inform themselves, must see that an enormous field of natural products and processes about to be explored has a number of industrial prizes and surprises in store ; scientific men who have to undertake the pioneering work in this field will find sufficient stimulus to effort in the promise of discovery." H. E. A.

EARLY CHALDEAN CIVILIZATION.

Cuneiform Texts from Babylonian Tablets, &c., in the British Museum. Part I. By L. W. King, M.A. Printed by order of the Trustees. Pp. iv + 50 plates. (Kegan Paul, Longmans, and others, 1896.)

RUMOURS must have reached the general reader from time to time of the "finds" of tablets which have been made by the natives in Southern Babylonia ; and it is a matter for congratulation that, judging by what we see in the volume before us, the results of these "finds" have been acquired by the Trustees of the British Museum. We have long been familiar with tablets of Assyria and Northern Babylonia, and it has long been evident that their contents were taken from clay documents which belonged to a much older period, and were the literary offsprings of a people whose early history had then disappeared in the mists of a remote antiquity. The

copies of the tablets, cones, &c., which Mr. King has just given us confirm this opinion, and we are brought face to face with a class of tablets to which, hitherto, we have been strangers. And just as the tablets are new to us, so, too, is their shape—for they are round, and resemble large bread-cakes more than anything else—and the eras in which they are dated are new, and the characters in which they are written are more complicated than any which we have hitherto seen. The texts upon them form public accounts and lists of revenue and produce which were drawn up for the public "record office" of the kings of the second dynasty of the city of Ur, about B.C. 2300; the kings most frequently mentioned are Bur-Sin, Ine-Sin and Gamil-Sin. Curiously, however, these tablets are not dated by regnal years, as are thousands and thousands of other documents, but by important events in the past history of the country, such as the capture of an enemy's city, or the invasion of an enemy, or the completion of some great public work, and unfortunately we have, at present, no means of telling *when* these events took place. Among the miscellaneous texts which Mr. King has given us we find a very important inscription in Accadian (No. 96-4-4, 2) containing an invocation to the goddess Nininsina to preserve the lives of Rim-Aku (Arad-Sin) and his father Kudur-Mabug, who flourished, probably before B.C. 2300, about one hundred years before Khammurabi succeeded in consolidating his kingdom in Babylonia. Another remarkable inscription is found on four clay "cones" (No. 96-6-12, 3), whereon we find recorded the name and titles of Mul-babbar, or if we read it as a Semitic name, Amêl-Shamash, a very early *patesi* or viceroy of Babylonia. We believe that this Mul-babbar is here met with for the first time. Still another most valuable text is found on the stone mace-head (No. 96-6-15, 1), where we have recorded a prayer to a god on behalf of one Nin-kagina, the son of Ka-azaggid, and of the viceroy under whom he served; the name of the latter is Nam-maghani, and he ruled over the city of Lagash, or Shirpurla, about B.C. 2500. It is an important fact that the name of Nin-kagina's father is given, and it would seem as if hereditary offices of high rank had already been established at that early period.

Want of space forbids our calling the reader's attention to many other important details in connection with these early texts; but it must be mentioned that their true value arises from the fact that they enable us to fill up part of the gap in our knowledge of the period which lies between the reigns of Khammurabi and Sargon I. of Agade. More than that, when worked out, these tablets will help us to understand the social fabric of the civilisation of the period, and will, no doubt, reveal the conditions of land tenure in Babylonia. It seems as if the land was managed for the kings or viceroys by the priests, and as if much of the administrative work of the country was deputed to them; that kings themselves also held priestly rank is also most probable. But although the forty tablets, &c., here published, yield so many results, it must never be forgotten that our knowledge of this period must be always fragmentary as long as a single tablet remains unpublished. We are very glad to see from the prefatory note to Mr. King's work, that other volumes of a similar character are to be issued by the Trustees of the British Museum, and we can only hope that the intervals between the appearance of the parts will not be long. They had already laid all cuneiform students under a debt of gratitude for their liberality in the publication of unremunerative books of Assyrian and Babylonian texts, and the present volume will make that debt greater.

In conclusion it may be mentioned that Mr. King's copies have been reproduced by photo-lithography, and that the work is therefore free from misprints which so often puzzle the reader, and lead him, sometimes, astray; the handwriting is clear, and neat, and careful—three qualities which should not be lightly esteemed.

HANDBOOKS OF PHYSIOLOGY.

Kirkes' Handbook of Physiology. By Prof. W. D. Halliburton, F.R.S. Fourteenth edition. Pp. 851. 8vo. (London: John Murray, 1896.)

IT is not very many years ago since "Kirke," as the book before us has been familiarly termed by many generations of students of medicine, had the field all to itself as a physiological handbook. During many years it had no rival; for the "Principles of Physiology" of the late Dr. W. B. Carpenter, although co-existent with it, was far too bulky to be regarded as in any sense a handbook. How different are matters in this respect now! What with Waller, Starling, McKendrick, Stewart, to say nothing of Foster, of Landois and Stirling, and of even bigger books looming in the distance, the student at the present day can take his choice; which he could not do then, for the only book offered to him in the days we are speaking of was the compilation by Dr. Kirkes, which, unlike most text-books, has been destined long to survive its original author. And an excellent compilation it was, founded upon the best work on physiology of its time, and, as some think, of all time, that by Johannes Müller; written, moreover, in a readable manner, so that the attention of the reader was easily maintained, and his interest in the subject never allowed to flag. But, alas! science is progressive, and a book on physiology may be ever so readable to-day but will not be read to-morrow, unless means are taken to bring its material "up to Saturday night." Thereafter comes the inevitable "editing," which may be all well enough so long as the author can himself undertake the repairs of his own fabric, but which is apt to render that fabric a very patchwork quilt of a book when it consists of the paste and scissors work of inserting a paragraph here and deleting a paragraph there, as was to all appearance the manner of preparing a good many of the round dozen of editions which intervened between the original book and the one we are considering.

The result was that the work became full of inconsistencies, amounting in some cases to grave errors; and at a certain period of its career it was so unfavourably regarded by the professors of physiology, that one of the most eminent of these is reported to have addressed his class in the following terms:—"If any gentleman present has purchased a copy of a book called 'Kirkes' Physiology,' I would advise him to take it out with him when he goes for a walk . . . and throw it over the highest

wall he can find." Nevertheless, in spite of this disfavour on the part of the professors, the book held its own in the favour of the student, although whether it did so entirely on its merits, or whether it was assisted by the deeply-rooted conviction which used to be current in the medical schools that "Kirke" was the book that was wanted by the examiners at "the College," is a question which we prefer to leave undecided.

But all this has now been changed. The patching process has been arrested; "Kirke" has been rewritten. And Mr. Murray may be congratulated on the choice he has made of an author—the term "edited" is very justly dropped altogether from the title-page. At the same time we may be permitted to drop a tear of regret that the long and original connection of the editorial staff of "Kirkes' Physiology" with "Bart's" should be ended, and that no one should have been found in that particular school worthy or willing, whichever it may have been, to undertake the task which Prof. Halliburton has now performed. We fancy that the late Dr. Kirkes would be no little taken aback could he behold the transformation which has been effected in his book. The whole arrangement is altered, so far as the physiology proper is concerned; the so-called "animal" functions are now taken first, and the "organic" functions next, while the general phenomena of nutrition are considered last of all. And the book bears the stamp—as is only natural it should do—of being written by one who is himself practically familiar with what he talks about; and this must be always the most important point in a text-book. Not that we would be supposed to undervalue "style," nor have we any particular fault to find with that of this book. But Prof. Halliburton has handicapped himself at the outset by endeavouring to keep up the reputation of "Kirke" for providing all that a student may require in histology and embryology, as well as physiology proper. In this he has, in our opinion, committed an error of judgment, for the chapters upon these subjects occupy a considerable bulk of the volume, which might reasonably have been devoted to considering some of the facts of physiology proper at greater length. The result is that the author has had in many subjects to adopt a style which is too concise to be thoroughly readable; and, indeed, the small amount of space which he has been compelled to devote to some subjects of considerable importance is a decided blemish on the book. Most subjects are quite as fully, and many subjects are much more fully treated of in the "Elements of Physiology" of Dr. Starling than in this one, although Starling's is a very much smaller book; and the difference between the treatment of physiological problems by Waller and our author is not less striking, and is in great measure due, no doubt, to want of the extra space which the omission of histology and embryology would have afforded. Nor has the student any real countervailing benefit, for he will be sure to go for his histology and embryology to books devoted entirely to those subjects, and which give the requisite information more thoroughly and satisfactorily than it can possibly be given in a general treatise of this kind. Although in this respect we think it may with advantage be modified, Prof. Halliburton has, nevertheless, produced an excellent book, and one which will be welcomed by many teachers and students. There are, however, one or two special points which ought not to pass uncriticised. One of these is the tendency of the author to describe a multiplicity of methods for obtaining particular results, irrespective of the relative value of such methods; and to give a multiplicity of opinions of physiologists on knotty subjects, without always taking a decided line himself. This tendency ought, we think, to be avoided in an elementary text-book, since the result is only to confuse the young student. Another point which we wish to notice is that the author has not, in our opinion, given full credit to other authors from whom he has borrowed either ideas or illustrations. Dr. Halliburton has, it is true, not carried this practice as far as is frequently done, and in most instances gives credit to whom credit is due: it is, indeed, probably by inadvertence that the immediate sources of his information are not everywhere acknowledged. But it is due to every author, and not less to the author of a text-book than to the author of a monograph, that, if his work be in any way appropriated, there should always be the completest acknowledgment of such appropriation. Probably no scientific authors would object to their work being thus utilised, while, on the other hand, most of them might naturally experience annoyance at its utilisation without acknowledgment.

OUR BOOK SHELF.

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India. Edited by W. T. Blanford. *Moths.* Volume IV. By Sir G. F. Hampson, Bart. Pp. xxviii + 594. 8vo. (London: Taylor and Francis, 1896.)

THE present volume includes the *Pyralidæ*, and an appendix to the earlier families of moths, thus completing the review of all the Indian moths, except the *Tortrices*, *Tineæ* and Plume Moths. The total number of species regarded as valid, exclusive of races or sub-species (many of which latter, it is reasonable to surmise, may hereafter be proved to be specifically distinct from the forms with which they are at present associated), amounts to 5618. The next volume of the "Fauna," it is announced by the editor, will likewise be devoted to insects, and will commence the series of descriptions of Indian Hymenoptera with those of the bees and wasps, by Lieut.-Colonel C. T. Bingham.

We congratulate Sir George Hampson on the completion (so far as the larger moths are concerned) of the important and useful work which he has undertaken. Of the execution of the present volume we need not say much, as we have already expressed our opinion freely, as regards the volumes which have preceded it; and the author's method, and the style of the work have undergone no alteration. We notice no falling off in either respect, nor are we more inclined to approve of such a dogmatic way of stating what cannot at present be more than an hypothesis, as the following:

"From the lower *Pyraustinæ*, with porrect palpi, and the third joint naked, arose also the other groups of *Pyralidæ*:

"The *Hydrocampinæ*, with vein 10 of the fore-wing stalked with 8 and 9:

"The *Pyralinæ*, with vein 7 stalked with 8 and 9, and vein 8 of the hind-wing free, giving rise to (*a*), the *Endotrichinæ*," &c.

We think that cautious evolutionists should simply confine themselves to saying that such and such groups

as exhibit a simpler structure than others, have probably diverged least from the primitive stock. We cannot too strongly insist upon the general recognition of the fact (self-evident though it be) that, in the present state of our knowledge, and in the almost total absence of palæontological evidence, our sketches of insect phylogeny, however useful and suggestive, cannot but be, to a large extent, purely tentative.

Some recent authors have regarded the *Crambidæ* as a totally distinct family from the *Pyralidæ*. Sir George Hampson recombines them, and divides the *Pyralidæ* into the following twelve sub-families: *Galleriinæ, Crambinæ, Schœnobiinæ, Anerastiinæ, Phycitinæ, Epipaschiinæ, Chrysauginæ, Endotrichinæ, Pyralinæ, Hydrocampinæ, Scopariinæ*, and *Pyraustinæ*.

Die Minerale des Harzes: eine auf fremden und eigenen Beobachtungen beruhende Zusammenstellung der von unserem heimischen Gebirge bekannt gewordenen Minerale und Gesteinsarten. Von Dr. Otto Luedecke. Pp. 643. Mit einem Atlas von 27 Tafeln und 1 Karte. (Berlin: Gebrüder Borntraeger, 1896.)

THIS elaborate Treatise on the Minerals of the Harz will be very useful, as a work of reference, to those who are in charge of mineral collections, and to all who are specially interested in those species with which the treatise deals. In it the author has placed on record the results of the observations made by him in the course of the last eighteen years, during which period he has examined the private and public collections of the region, and has visited the Harz localities both to satisfy himself on the spot as regards the existence of the minerals at the places mentioned, and to obtain information as to the modes of occurrence; these visits were facilitated by the nearness of the district to Halle, of which University Dr. Lüdecke is a distinguished professor. Further, the author has incorporated the results of the study of Harz minerals by other mineralogists. In the case of the more important species, such as Galena and Copper-pyrites, a brief sketch is given of the geological features of the districts in which the minerals occur. The treatise is accompanied by an atlas of twenty-seven plates (chiefly crystal figures and stereographic projections) and a very clear map of the region, photographically reduced from the one prepared by Borchers in 1865. Prof. Lüdecke has done a considerable service to Mineralogy by the publication of the results of so thorough an examination of this important mineral region.

The Wonderful Universe. By Agnes Giberne. Pp. 128. (London: Society for Promoting Christian Knowledge, 1897.)

TO the class of readers which finds pleasure in being oppressed and bewildered with information as to the "wondrous far distances," and especially to the members of it possessing a sentimental bias, Miss Giberne's book will successfully appeal. Among the titles of the eleven chapters are "The Silver Moon," "Fair Venus," "Red Mars," "Twin Giants," and "Stars of Light." What Miss Giberne has to say on these and other subjects comprised in her book can usually be depended upon; and, as might be inferred from the quoted titles, she aims at making her descriptions attractive. In the latter attempt, however, she is not altogether successful. A sprinkling of poetical extracts, a few lapses into the religious aspects of astronomy, some lugubrious humour, and a number of statements as to how long it would take to go to the moon and other places in an express train, make up much of Miss Giberne's latest volume. Still, the fact that the information can be trusted, and that it is very simple, is a recommendation.

There are no illustrations, not even in the chapter on "How to Learn the Heavens," and there is no index. A book on astronomy published with such omissions hardly possesses the qualifications for success.

The Story of Forest and Stream. By James Rodway, F.L.S. Pp. vi + 202. (London: George Newnes Limited, 1897.)

IN this little book Mr. Rodway sketches, in his best style, the life of trees in wood and forest, and indicates the lessons that it teaches. He points out the benefits derived by man and other animals from forests and streams, imparting the information in pleasing language, and presenting nature in many instructive aspects. The twenty-seven illustrations are the best that have yet appeared in any of the volumes in the Library of Useful Stories, to which series the present book belongs.

Mr. Rodway naturally devotes the largest share of attention to the forests of South America, for he is most familiar with the conditions which obtain in them. On this account, however, the plant-life described is somewhat limited, though here and there comparisons are made between the floras of the old and new worlds. A more appropriate title for the book would have been "The Story of Tropical Forest and Stream."

Quelques observations sur les Muscles Peauciers du Crane et de la Face dans les Races Humaines. By Théophile Chudzinski. Pp. 90. (Paris: Masson, 1896.)

THIS work gives an account of the arrangement of the superficial muscles of the head and neck in the different races of men. The muscles are described, and a series of measurements given for each in the different races. The general conclusion is what one would expect; namely, that these muscles of the superficial fascia are most marked in the black races, least so in the white, while in the yellow races they are intermediate in their development. The facial muscles of the negro are found to closely resemble those of the gorilla in their great development. M. Chudzinski draws attention to the diagramatic manner in which the muscles of expression are usually figured, and notes particularly certain very superficial layers which it is customary to remove in defining the edges of the muscles. The twenty-five figures, which are given at the end of the text, illustrate the comparative development of the muscles as seen in dissections of the heads of different races.

LETTERS TO THE EDITOR.

The Meaning of the Symbols in Applied Algebra.

IF I had made a slip of the pen of the kind suspected by Mr. Cumming (p. 198), it would have been a serious error, because it constituted the essence of what I was writing about. I was sure that a number of teachers did not believe it, and I am obliged to Mr. Cumming for giving me another opportunity of emphasising what I believe to be a vital matter. He says "the multiplication of one length by another length [or, more generally, of one concrete quantity by another] is abhorrent to the mind of" certain mathematicians. Quite true, I know it. The idea was abhorrent to the mind of the late Mr. Todhunter, and I think that Prof. Greenhill has expressed himself in the same sense. But what then? That is exactly why the idea requires driving home; and until it is driven home there will be no real clearness or simplicity in dealing either with physical quantities themselves or with their numerical specification in terms of given "units."

Mr. Cumming says that "$2Rh = d^2$ is an algebraic equation, and as such its symbols express numbers, not things." Whereas I say that truly it is an algebraic equation, and as such its symbols may express things and not numbers. A relation between numbers is an arithmetical equation, and is appropriate to the pure mathematician; by him algebra was first used, and he still clings to the ancient practice; but physicists have now made a perfectly legitimate step onwards and extended the scope of the science. Applied mathematics is concerned with things, and its symbols may properly be taken to represent concrete quantities (see, for instance, NATURE, vol. xxxviii. p. 282).

Mr. Cumming says that the equation is true in any units; but if he gave his boys R in metres, h in inches, and d in yards, or if he used it for finding the curvature of a lens, or the thickness of a Newton's-ring film, telling them at the same time that the symbols only represent numbers, they might be in a fog. A perfectly unnecessary fog, and that is the serious part of the business. Artificial difficulties obstruct the path of the beginner in regions which are quite easy, and hence it is that his progress into higher regions is so slow. Such difficulties need not exist. The golfer who keeps on the straight course is untroubled by bunkers and obstacles which infest the path of the wild driver.

If Mr. Cumming can spare time to reconsider the question, I know it needs an effort, *experto crede*, I am sure it will repay him.

I call the attention of those physicists who are already familiar with the straightforward mode of dealing with concrete quantities to the remarkable letter, by Mr. C. S. Jackson of the R.M. Academy, Woolwich, immediately preceding Mr. Cumming's; and, as he asks me a definite question, I answer $s = w/v$.

The Force of a Pound.

MAY I suggest to Prof. Perry that it might be well to imitate the enemy's tactics and give a name to the unit of inertia on the pound-force system.

I would propose that, on this system, any piece of matter having the unit quantity of inertia or sluggishness be, for dynamical purposes, termed a "slug."

The foot-pound (force)-second system might then be equally well styled the foot-slug-second system, and under the aspect implied by this name would stand on precisely the same footing as the centimetre-gram-second, or the foot-pound (mass) -second system.

A "slug" would be an instructive object to contemplate. Its virtues would be pretty accurately embodied in a a 32-lb. shot, which, in fact, is manufactured solely for the sake of its inertia, and is a body not unfamiliar even to athletic undergraduates in our universities.

I have taught dynamics for many years, both to unprofessional students and to engineers, and have remarked that the unit difficulty is felt far most strongly by the latter. This I attribute in part to the relative inadequacy of the linguistic training which many of my engineering students have received before entering on their professional studies. They are not well able to disentangle verbal confusions, and are resentful of them. Consequently a liability to trip, arising from some ambiguity of terms, which would be a stimulating challenge to a student of wider training, is an unmitigated nuisance to the engineer, who has no interest in this kind of thing, and does not wish to be bothered by it.

The difficulty is one of language and not of dynamics, and I am quite in sympathy with Prof. Perry's desire to get rid of it, and should adopt without hesitation a good text-book which employed the pound as the only unit of force, if I knew of such.

It should always be remembered that, to most students, the study of dynamics is the study of the new and unfamiliar property of inertia, and it is only reasonable that the new quantity should have a unit with a new and unfamiliar name.

Torquay, January 4. A. M. WORTHINGTON.

Sir William MacGregor's Journey across New Guinea.

IN NATURE of December 17, p. 157, you publish an article describing Sir William MacGregor's interesting journey across the South-eastern Peninsula of New Guinea, by Mr. J. Thomson. As he has introduced some reference to my work in the Possession, perhaps you will kindly allow me space for a few observations. The names of seven travellers, besides my own, are mentioned whose attempts "to explore the Alpine region of the Owen Stanley Range" have "resulted in signal failure." More than one of us, however, *did* reach the Alpine regions of the range, though none of us ascended Mount Owen Stanley. And I cannot think that any of those who made the attempt will feel any discredit attaching to them on that account, any more than attaches to Sir William MacGregor that he could not reach the mountains beyond the sources of the Fly River. That Sir William was the first to scale Mount Owen Stanley is true, and he deserves all the *kudos* he has received for his exploit. Yet the success which attended his efforts was in no small measure due to the information gathered by his forerunners, and even by their "signal failures." Each traveller made it easier for his successor; and Sir William mounted on the backs of all who had preceded him, however much the historiographer for New Guinea may try to ignore their efforts. The reason why some of us who made a not ill-considered effort at great personal expense to reach the summit of the Mount, failed in accomplishing all we desired, was chiefly one of money. Sir William, who has the resources, the steamers and the launches of the Possession at his back, and has besides the prestige of "Great Chief" over the natives—no mean factor in the exploration of such a country—and can call upon his officials in all quarters for aid, is in a very different position from a private traveller dependent very largely (I speak for myself) on his own resources, and *ought* to accomplish far more than any other traveller.

Mr. Thomson goes on to say: "It may be pointed out that there seems no doubt that Mr. Forbes did not see the highest crest of the mountain from his nearest approach to it, and it is almost certain that he could not have obtained access to the crown of Mount Victoria [Mount Owen Stanley] along the south-eastern spur of it. Concerning this accessible spur, which Mr. Forbes proposed ascending, Sir William MacGregor says, it is a mighty precipitous buttress, exceeding 12,000 feet in height, 'bristling with peaks and pinnacle-like rocks, and contains hundreds of inaccessible crags and precipices.'" Mr. Thomson's doubts about what I saw or did not see from my nearest approach to Mount Owen Stanley, are merely the expression of one having no personal knowledge of the country. But if Sir William MacGregor—for whose explorations I have the highest admiration—has said what Mr. Thomson puts into his lips at the close of the above extract, it is quite plain that he is not referring to the same feature that I have described. I took—and, if I mistake not, have published—a round of bearings upon "the highest crest," the most familiar object in my horizon for months. I approximately fixed the positions of and placed on my map names to these same crags and peaks; but the Lieutenant-Governor, following a custom not infrequent with him in regard to the geographical nomenclature of his predecessors in this and other regions of New Guinea, has renamed them. The "accessible spur" mentioned by me, however, was not "a mighty precipitous buttress"— a feature, according to the description, one would think, not altogether unrecognisable as such—nor yet a Primrose Hill; but it was a negotiable slope all the same, and on a less incline than some others ascended by me in the same country.

In conclusion, I cannot help again drawing the attention of cartographers and geographers to the fact that Sir W. MacGregor, after all that has been expressed at the Royal Geographical Society, and publicly by many writers, on the point, still claims for himself the honour of naming the chief mountain in the Possession, by persistently calling it Mount Victoria, instead of Mount Owen Stanley as it was christened nearly half a century ago by Huxley, and has been so inscribed on every map all those years. Prof. Huxley himself told me that the feature on which he bestowed the name Owen Stanley —in honour of as distinguished a commander and explorer as has ever sailed in those waters—was not the range, but the mountain, whose summit he saw rising clear above the clouds one early morning when the *Rattlesnake* was lying in Redscar Bay. Its position and altitude were then accurately determined.

HENRY O. FORBES.

The Museums, Liverpool, January 4.

Shooting Stars of January 2.

THE shower of shooting stars seen by Dr. H. C. Sorby on the morning of January 2, formed evidence of the return of a well-known meteor stream which has its radiant in Bode's modern

constellation *Quadrans Muralis*, about 20° north of Corona, and between Boötes and Draco. The shower seems to have been in pretty strong evidence at its recent return, for Prof. Herschel observed some fine long-pathed meteors from it during the hour preceding midnight on January 1, and Mr. Milligin, of Belfast, writes me that, on the morning of January 2, he recorded twelve of its meteors indicating a radiant in the usual position at 230° + 52°. Though often escaping notice, the January meteor stream sometimes furnishes a really active display, and an observer may count thirty or forty shooting stars in an hour. They are brighter than the average of such objects, and the radiant being low during the greater part of the night, they have very extended flight, which adds to their conspicuous appearance.

Bristol, January 8. W. F. DENNING.

The Svastika.

IN your report of the Presidential Address, Section H, Anthropology, at the British Association, I observe on p. 529 that, "It is in the same Anatolo-Danubian area—as M. Reinach has well pointed out—that we find the original centre of diffusion of the Svastika motive in the old world."

I trust that you will permit me to point out that this type of ornament is not uncommon among our Pre-Aryan savage races, and I enclose a rubbing of one, off a large flat engraved hair-pin

worn by the women and grown-girls of the extreme eastern Naga group, near Margharita, Upper Asam.

These bone hair-pins are peculiar, and the patterns do not vary. I describe them on p. 6 of my paper in the *Journal of the Asiatic Society of Bengal* (vol. lxv. part iii. No. 1, 1896), copy of which I send.

A complete costume of one of these Naga women has been sent to Dr. E. B. Tylor, Oxford Museum, and I have no doubt a *Svastika* will be found on one of the hair-pins.

As the Aryan influence has not yet reached these hill savages, many tribes of whom are still head-hunters, I presume the dictum above quoted as to the home of the Svastika will be modified.

In your issue of April 30 last, on p. 605, I drew attention to the fact that "Megalithic folk-lore" still survives here among our Junglis. No notice has, I see, been taken of the matter: surely it is noteworthy? S. E. PEAL.

Sibsagar, Asam, December 5, 1896.

A Critic Criticised.

THERE is a tendency among critics to condemn a book for not comprising what it was not intended to contain. Such critics have a preconceived notion of what a writer should have included in his treatise; they glance through the pages in a superficial manner for what they think should be there, and not finding such topics expressed to their mind immediately condemn the treatise.

This pernicious habit of critics is well illustrated by recent criticisms (NATURE, p. 545, October 8, 1896; *The Electrician*, p. 637, September 11, 1896), of Prof. Bedell's book, "The Principles of the Transformer," by Frederick Bedell, 1896, on the theory of the transformer. A writer in NATURE sees nothing good in the treatise because it does not enter fully upon the practical details of transformers with iron cores. To do this, Prof. Bedell would have been compelled to greatly increase the size and scope of his book. It was plainly his object to outline, so to speak, the scaffolding of the edifice, and to give in a clear manner the fundamental equations upon which the discussions of transformers rest, and to illustrate the use of graphical methods in such discussions.

Before the appearance of Prof. Bedell's treatise, the student was compelled to rely upon books which were illogical collections of articles originally published in electrical journals, and hastily thrown together in a book form. A just critic should recognise the endeavour of Prof. Bedell to bring order out of chaos, in presenting the fundamental equations used in discussions of alternating currents in such a clear and instructive manner. JOHN TROWBRIDGE.

Harvard University, Cambridge, Mass.

IN the mind of a reader acquainted with the literature of the subject, and having read also the book, to which reference is made in Prof. Trowbridge's letter, the somewhat exaggerated statements in his note can only excite surprise. An author must, to a large extent, be judged by the claims he makes for his work. If the book in question had been entitled "A Mathematical Treatise on Harmonic Currents," it would have been placed on unassailable ground. The writer of it, however, selected a title which certainly claims for it a practical character. His treatment of the subject is largely confined to a discussion of the properties of transformers and condensers in which the real magnetic and dielectric qualities are ignored. The result of such a mode of dealing with the subject is to present a series of interesting mathematical problems, but they have the same relation to the real apparatus that problems concerning weightless pulleys and levers have to the operations of the block, tackle, and crowbars of actual life. THE REVIEWER.

The Union of Nerve Cells.

TO a note by Mr. Alfred Sanders, in a recent number of NATURE (p. 101), criticising the assertion by Ramon y Cajal, that the nerve cells are independent units, and never form anastomoses between one another, I would like to remark that Cajal is not alone in forming such a conclusion. The general consensus of opinion of many other practical neuro-histologists favours the same conclusion. There is no doubt that many cases, such as that which Mr. Sanders mentions finding in *Tropidonotus natrix*, occur; I have found more or less similar ones in the brain of the honey-bee. But when one considers that two fibres in contact would, if thoroughly impregnated, present the appearance of continuity, it is more or less evident that one cannot be guided in forming a decision by such cases as those cited, and that one must depend upon the immensely larger number of cases in which the terminations of fibres are found near, but not in contact with, one another. This is to be said of all preparations by either the various Golgi, or by the methylen-blue, methods, and is something to which I have elsewhere called attention ("The Brain of the Bee," p. 161–2, *Journal of Comparative Neurology*, vol. vi.). F. C. KENYON.

Philadelphia Academy of Natural Science.

I MAY remark, in reference to Mr. Kenyon's letter, that my object in sending the communication on p. 101 was not to criticise Ramon y Cajal's conclusion that no cells of the nervous system ever anastomose, which I have no doubt is, as a rule, correct, but simply to place on record a rare exception, the only one that I have found in several hundred sections, prepared either by the chrom-osmium silver or mercurial methods, of the nervous system of the lower vertebrata. There is a slight misunderstanding on Mr. Kenyon's part, due, probably, to the way I put it. The two cells to which I referred were not joined by the extremity of each dendrite, but by the dendrite of one cell joining, after a short course, the body of the other cell, and even projecting into it. I found a case somewhat similar to this some years ago in the Ceratodus, where two cells of the spinal cord were joined by a broad protoplasmic band; but this specimen was treated in the old way, by being stained with some aniline dye. A. SANDERS.

Two Corrections.

THERE is a slip of the pen, or of memory, in the description of the shrine of Boro Budur, in Java, as "rock-hewn," in your issue of yesterday (p. 228). The shrine is indeed a natural hill, but cased in cut masonry, which bears all the sculptures. I happen to possess the great Dutch work on it, with plans, so can speak with some confidence. Another slight "erratum" in the same number (p. 234), is the description of the Bombay Observatory Staff as native "with the exception of Mr. Moos." Mr. Moos must, by his name, be a Parsi of Western India. There are many Parsis of that surname, and, particularly, several scholars and scientific men. W. F. SINCLAIR.

January 8.

CELESTIAL EDDIES.

I PROPOSE in the present paper to discuss the question whether the long-exposure photographs of Dr. Roberts and others, justify or negative the view, founded upon a large mass of spectroscopic evidence, which I put forward in 1887, before any of them had been published.

The view in question was thus stated :[1] "The brighter lines in spiral nebulæ, and in those in which a rotation has been set up, are in all probability due to streams of meteorites, with irregular motions out of the main streams in which the collisions would be almost *nil*."

I was careful to state that Prof. G. Darwin, when discussing the gaseous hypothesis of Laplace, had already pointed out that "the great mass of the gas is non-luminous, the luminosity being an evidence of condensation along lines of low velocity, according to a well-known hydrodynamical law. From this point of view the small nebula may be regarded as a luminous diagram of its own stream-lines."[2]

At the time I wrote in 1887, the nebula in Andromeda was not considered to be a spiral nebula. The most striking representation of it was due to Bond, who drew special attention to two black streaks running nearly parallel to the longer diameter.

It may also be added that in 1887 we knew nothing for certain about its spectrum.

In 1888, Dr. Isaac Roberts published his most admirable long-exposure photographs, which at once established the spiral nature of the nebula ; and in the same year the complete discussion of the spectroscopic observations made up to that time led me to predict that if the nebulæ were carefully observed we should find in them, sooner or later, indications of the substance which makes the comet spectrum so very distinct and special. In 1889, that is in the next year, the spectrum of carbon was discovered by Mr. Fowler and Mr. Taylor in the nebula of Andromeda.

I will take the photograph first. The plane of movement in the spiral system is so situated that from our point of space we look at it obliquely ; hence the nebula appears very elliptic. Still there is no difficulty in seeing that the various streams round the centre of condensation are all of them of a spiral form, with certain condensations interspersed here and there along them.

We have a condensation in the prolongation of one of the spirals, and there is considerable clustering of apparent stars along the stream lines. It is important to indicate that we have in these appearances, not signs which tell us of the existence of matter merely—so that when we have not the appearances we would be justified in supposing that there was no matter—but an indication of *movement* in matter, so that we may imagine that this nebula and others like it do probably consist of something extending enormously in space beyond the indications which we see, for the reason that near the centre the movements are more violent than they are towards the outside. We are there face to face with the idea that we have to deal with orderly movements. If the movements are orderly, it means that the movements of the constituent particles of the swarm, all of them, or most of them, will be in the same direction ; in that case we have the condition of minimum disturbance, and therefore the condition of minimum temperature.

In short, not only have we regular spirals, but in addition to the spiral system there seems to be revealed irregular masses of nebula near both ends of the major axis. Where more than one stream seems to be contending, the brilliancy is enhanced, and much irregular luminosity is apparent. On the other hand, in the part of the main nebula most free from these irregularities the spirals are almost invisible.

[1] *P.R.S.*, November 17, 1887, p. 153.
[2] NATURE, vol. xxxi. p. 25.

Next for the spectroscopic observations.

The chief argument urged in favour of the gaseous nature of the nebulæ now is the existence of hydrogen and helium in the planetary nebulæ and in such a nebula as that of Orion ; the unknown form of nitrogen has no longer any votaries.

But if the spiral nebulæ be gaseous, why do they not give us the spectra of hydrogen and helium? The spectrum of the nebula of Andromeda is practically the spectrum of a comet, and therefore we are justified in considering it as built up of cometary materials. Now these, as is generally conceded, are meteoritic in their nature.

But this is not all the evidence bearing upon this question, even so far as regards the nebula we are now discussing. Not many years ago a new star was observed

FIG. 1.—Nebula of Andromeda, 1887.

in the nebula, and the difference between the spectra of the new star and of the nebula itself was merely the addition of the lines of hydrogen! On the meteoritic hypothesis this is easily explained by an increased number of collisions lasting for a time : on the gaseous hypothesis an explanation is not so easy.

If it be granted that we are really dealing with streams of meteorites, all the new phenomena revealed to us by Dr. Roberts' photographs receive a simple and sufficient explanation, especially the apparent condensations here and there, which are not condensations of matter necessarily but *loci* of greater disturbances caused by crossing streams.

The next considerable revelation was obtained from the photograph, taken in 1889, of the spiral nebula—long recognised as such—in Canes Venatici, certainly one of the most wonderful spiral nebulæ in the heavens. It is all the more striking because this is a nebula which we

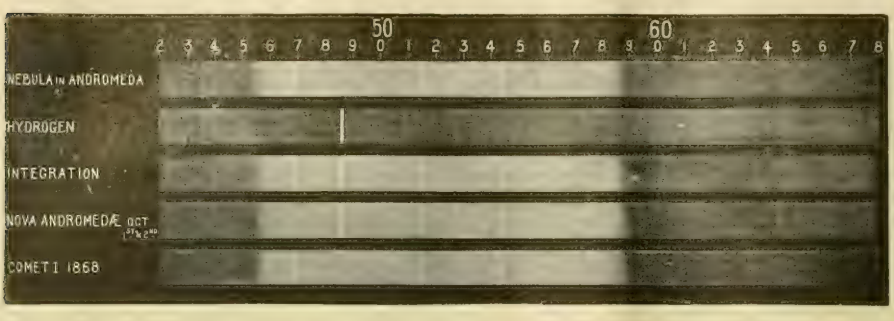

FIG. 2.—Spectrum of the nebula in Andromeda compared with Nova Andromedæ and comet. The flutings common to all are those of carbon.

look down upon; we see it in plan; we are, so to speak, at the pole of the system, so that it is not foreshortened.

There is no question about the wonderful spirals being connected with the central condensation and stretching

FIG. 3.—The spiral nebula in Canes Venatici, from a photograph by Dr. Roberts, 1889.

towards it. I call attention to the points of condensation along one of the spiral branches, and where we get the possible intrusion of two spirals one on the other we see a confused mass of light. Now, if we imagine ourselves dealing there with a mass of pure gas, whether it is hydrogen or nitrogen or ammonia—that is, a combination of both—or any other, it would be extremely difficult to see why there should be any change of temperature in different parts of that mass; but the moment we assume that we are dealing with cool materials—meteoritic dust—we see that such a picture as this is important, for the reason not that it shows us what is there, but because it shows us what is going on there, as already pointed out in relation to the nebula of Andromeda. The bright spots do not represent the presence of matter merely, and the dark ones its absence; but the brighter portions represent the intersection of stream lines where collision is possible—the intervals those regions where collisions are less likely. We can gather from the very configuration of this system that if all the dust, or meteorites, or conglomerations of particles, whatever they may be, are going the same way, there will be a condition in which we shall get a minimum of collisions, and therefore a minimum of temperature. If the movements are quite orderly and in the same direction, we must not expect to get any very great disturbance, and therefore—if these disturbances produce high temperatures—we shall not expect to get indications of any particularly high temperatures.

The important point is that here we get apparent stars arranged along the spirals.

Dr. Roberts writes as follows:—

"The photograph shows both nuclei of the nebula to be stellar, surrounded by dense nebulosity, and the convolutions of the spirals in this as in other spiral nebulæ are broken up into star-like condensations with nebulosity around them. Those stars which do not conform to the trends of the spirals, have nebulous trails attached to them."[1]

Strikingly similar to the above is the photograph of M 74 Piscium taken by Dr. Roberts in December 1893; and here again it is also a question of apparent stars.

"The photograph shows the nebula to be a very perfect spiral, with a central stellar nucleus and a 15 mag. star close to it on the south side. The convolutions of the spiral are studded with many stars and star-like condensations, and on the north preceding side there is a partial inversion of one of the convolutions, which conveys the idea of some irregular disturbing cause having interfered with the regular formation of a part of that convolution."[2]

In Messier 101 Ursæ Majoris, which was photographed in May 1892, we have another case in which the convolutions are broken up into star-like condensations.[3]

[1] Roberts' photographs, p. 85. [2] *M. N.*, vol liv. p. 438
[3] Roberts' photographs, p. 89.

I wish to point out that from the centre of the condensation the luminosity gradually gets less and less until at last we have no luminosity greater than that of the surrounding sky. In the nebula itself we find exquisite spirals, starting apparently from different points, and

FIG. 4.—Messier 74 Piscium, 1893.

gradually coming towards the centre, and if we look along these spirals we see that the star-like masses, *which may not be stars*, are in many cases located on the spirals, representing apparently minor condensations, each itself

FIG. 5.—Spiral nebula, Messier 101 Ursæ Majoris.

being probably brighter than the other parts because it is more disturbed.

So much, then, for the autobiographical records we now possess of some of the most perfect spiral nebulæ in the heavens.

We see that they all resemble perfect *eddies* in appearance; the question arises, are they perfect eddies in fact? On the meteoritic hypothesis they may well be so, for if moving streams of meteorites encounter resistance to their motion due to disturbances by other masses, the sheets of meteorites are bound to behave like sheets of water; in any case, the *onus probandi* lies with those who hold the contrary view. But in these celestial maëlstroms there are bound to be smaller eddies; and, if Swift had had the opportunity of studying Dr. Roberts' photographs, a more grandiose image might have replaced that in his well-known lines—

> "So naturalists observe, a flea
> Has smaller fleas that on him prey,
> And these have smaller still to bite 'em,
> And so proceed *ad infinitum*."

The question is well worth asking, not only to enable us to explain the photographic and spectroscopic phenomena, but also because we seem to be in presence of forces which must ultimately result in a true star *with rotation*, a concomitant of star life which is not easy to explain,

FIG. 6.—M 33 Trianguli.

and which Lord Kelvin has shown would certainly *not* be produced by collisions of two finished cosmical bodies.[1]

There is another spiral nebula, however, which may carry us a little further along the same line.

In M 33 Trianguli we have something apparently different from those that have preceded; so much so, that Dr. Roberts, who till quite recently has remained silent with regard to the physical origin of the more regular spirals, has suggested that we may here be in presence of meteoritic collisions.[2] He writes:—

"It will be observed that there are two large, very prominent spiral arms, with their respective external curvatures facing north and south, and that the curves are approximately symmetrical from their extremities to their point of junction at the centre of revolution, where there is a nebulous star of about tenth magnitude with dense nebulosity surrounding it, and elongated in *north* and *south* directions. Involved in this nebulosity are three bright stars and several faint nebulous stars; the two arms also are crowded with well-defined stars and faint nebulous stars with nebulosity between them; and

[1] *Proc. R.I.*, xii. p. 15. [2] *M. N.*, vol. lvi. p. 70.

it is to the combined effect of these that the defined forms of the arms are due. Besides these two arms there are subsidiary arms, less well defined, and likewise trending towards the centre of revolution, and are constituted of interrupted streams of faint stars and nebulosity intermingled together; many of the stars are nebulous, and many are well defined but small. The interspaces between the convolutions are more or less filled with faint nebulosity, having curves, rifts, fields, and lanes, without apparent nebulosity in them. They are like the interspaces in clouds of smoke, and cannot be classified.

"There are outliers of nebulosity with many small well-defined and nebulous stars involved in them, and there are also isolated nebulous stars on the extreme boundaries of the nebula; but the evidence is strong that they are all related to the nebula.

"It is by the study of the photographs, and not by descriptive matter, that we can form a true conception of the character of this nebula; from which we shall be justified, even now, in drawing some inferences as to its formation and further developments. To this end I may be permitted to suggest the following.

FIG. 7.—H 84 Comæ.

"We know, with a reasonable amount of certainty, that both nebulous and meteoric matters exist in space; and we also have some evidence that bodies in space have come into collision.

"From these premises we may infer that this nebula is the result of a collision of some kind; and we can imagine collisions of at least three kinds possible; namely, (1) between two stars, (2) between two nebulæ, (3) between two swarms of meteorites.

"In the case of this nebula, which (if any) of the three possibilities mentioned seems to us the one most probable to have happened? Much might be said in favour of each of these suggestions, but I shall not at present enter into details, though I think we could readily imagine that the collision of two swarms of meteorites, moving in opposite directions, one from the *south following* and the other from the *north preceding*, would account for the spiral appearance, the rotatory motion, and the smashed and scattered state in which the nebula is shown to us upon the photographs."[1]

[1] *M. N.*, vol. lvi. p. 70.

It is worth while to point out, in connection with the argument in favour of the meteoritic nature of spiral nebulæ, that there are other nebulæ representing streams in space to which it seems almost impossible to attribute a purely gaseous origin.

This branch of work is so young, that there has not yet been time to bring a crucial test to bear on these "stellar condensations" to which reference has been made. *If they could be shown to be short-period variables, then their true stellar nature would be at once negatived.*

We have already in two instances obtained important evidence on this point. In 1889, Dr. Roberts was good enough to allow me to enlarge a photograph of the nebula of Orion, on which there had been a double exposure. I pointed out to Dr. Roberts that the variability in some of the stars was suggested. Although the exposure was a double one, some of the images were single and there were *inversions* in the intensities of the double images. Dr. Roberts made a minute examination with the following results:[1]

"On examination of the dual stellar images on the photograph the eye immediately detects that ten of them have undergone considerable change in brightness or

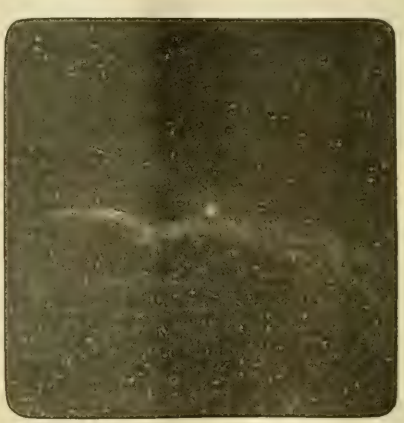

FIG. 8.—Nebula near 52 (*k*) Cygni.

magnitude during the interval of five days which elapsed between the two exposures. In three of the ten stars, the brightness has increased to the extent of from one-fourth to one-third the measured diameter of the stellar photo-image, and one star appears on the second exposure where none is shown on the first exposure. Six of the ten stars have diminished in brightness during the interval to the extent of from one-fourth to four-tenths, the measured diameter of the photo-image." . . .

"I have with due care examined the film of the negative under the microscope in order to see if any defect or evidence of defective sensibility on parts of the film could be traced so as to account for the variability in the brightness of the stellar images, but I could not find any such evidence, and I would of course have repeated the photographic experiment if the state of the sky at any time during the past twelve months had permitted. Those who possess the necessary telescopic power may study by eye observations the variability in these stars, and it is one of the functions of the photographic method to point out where eye observations can with advantage

[1] *M. N.*, vol. l. p. 316.

be applied in search for special knowledge, and these ten stars are now indicated for that purpose."

The next cases are those afforded by the variability of stars in some globular star-clusters recently photographed at Arequipa with the 13-inch Boyden telescope. An extraordinary number of variable stars was discovered. The *Harvard Circular*, No. 2,[1] states :—

"At least eighty-seven of the stars in the cluster M 3 (N.G.C. 5272), in Canes Venatici, have been found to be variable, and in some cases the change of light amounts to two magnitudes or more. In the cluster M 5 (N.G.C. 5904), forty-six variables were found, out of 750 stars examined, so that they form about 6 per cent. of the whole ; of the sixteen stars, contained in a circle 110" in diameter, six are variable. Smaller numbers of variables have been found in other clusters, but in other cases not a single variable has been detected out of the hundreds of stars which have been photographed ; the conditions of the search, however, not taking account of long period changes. In general, no variables have been found within about one minute from the centres of the clusters, on account of the closeness of the stars, and none are more than ten minutes distant from the centres. Some of the newly-discovered variables have short periods, in some cases of only a few hours. Thus, five photographs of N.G.C. 5904, taken at intervals of an hour on July 1, 1895, give for the magnitude of a star about three minutes of arc preceding the centre of the cluster, 14·3, 13·5, 13·8, 13·9, and 14·3 ; four plates, taken at similar intervals on August 9, gave the magnitudes 14·2, 14·6, 14·8, and 15·0."

A special investigation has since been made of the variables forming part of the cluster M 5 Serpentis, N.G.C. 5904 (*Ast. Nach.*, 3354). Forty-five photographs of this cluster have been measured by Miss Leland, and the measures include the greater portion of the forty-six variables previously discovered. The periods of these variables are in general very short, not exceeding a few hours. One of these, designated No. 18, which follows the centre of the cluster about 6′ and is south 5′, has a probable period of 11h. 7m. 52s., or 0·4638 days. The coordinates of the light curve of this variable are as follows :—

Days.	Mag.	Days.	Mag.
0·00	13·50	0·25	14·73
0·05	13·87	0·30	13·73
0·10	14·35	0·35	14·72
0·15	14·70	0·40	14·65
0·20	14·72	0·45	13·56

It thus appears that the star remains about minimum brightness during half the period, while the maximum luminosity is of relatively short duration ; the decrease in light is rapid, but the rate of increase is still more rapid, as it should be. The succession of changes does not seem to correspond with those of any previously known class of variable stars.[2]

Now, since the presence of real nebulous material in some star clusters is accepted by many authorities, there seems ground for ascribing the phenomena in the nebula of Orion and in the star clusters to the same cause, and in attributing them to mere star-like appearances due to collisions. A variability of the kind described extending over a few hours or a few days is to me unthinkable in a "star," properly so-called, that is, a body like our sun, and I have no hesitation in expressing my firm conviction that such variability can only be simply and sufficiently explained by the cause assigned for it by the meteoritic hypothesis—a clashing together of streams of meteorites.

If the evidence that the apparent stars are really denser and more disturbed meteoritic swarms is accepted, the view that the nebulæ are gaseous must fall to the ground, because the denser material of the "stars" must be the same as that which was least dense, that is, sparse in the first instance.

I am glad, finally, to be able to state that Dr. Roberts, to whose continuous activity and marvellous skill the world of science is so much indebted, in a paper read at the meeting of the British Association at Liverpool this year, stated his opinion that the origin of the various star-like condensations in the spiral nebulæ is "more probably" meteoritic than gaseous in its origin. The line of argument which has led him to this conclusion will be gathered from the following brief analysis of his communication :—

He draws attention to the remarkable groups, curves and lines of stars that are clearly shown upon a photograph of the sky in the constellation Auriga, which was taken with an exposure of the plate during ninety minutes. Some of them are constituted of bright stars of nearly equal magnitude ; some are of faint stars, also of nearly equal magnitude ; some are of both bright and faint stars, and there is much regularity in the spacing distance between the stars in the several groups. These appearances are persistently found upon all photographs taken with long exposures of the plates in any part of the sky where the stars are numerous, such as Cassiopeia and Argo.

"What explanation," he asks, "can be offered to account for the grouping of the stars other than the assertion that they were from the beginning so placed?" He then brings forward the evidence furnished by the spiral nebulæ similar to that I have given above, and which I brought together more than a year ago.

He then goes on :

"I would submit that the evidence, part of which has now been laid before us, is reasonably conclusive that some, if not many, of the stars which we see in curves and in groups strewn over the sky have been formed in the manner which I have pointed out. There are, besides this, other methods of stellar evolution pointed out on other photographs, such as condensations into stars of nebulæ which have not, at present, symmetrical structures and of globular and annular nebulæ.

"The question will naturally present itself to us : If it be true that stars are evolved from spiral and other forms of nebulosity, whence came the nebulous matter? We can answer with confidence that it exists very largely and over extensive areas in many parts of the sky ; and that it exists there in the form of gas, or, more probably as Prof. Norman Lockyer urges in his 'Meteoritic Hypothesis,' of meteors or meteoric dust."

Dr. Roberts' reference to my work is very encouraging, since there are few workers in science whose researches have so close a bearing on the views I have put forward. For my own part I feel that the totality of the observations above recorded is all highly suggestive of meteoritic action, and I can only in conclusion express my belief that before very long as striking evidence of variability will be found in the stars in the spiral nebulæ, as the Harvard observers have obtained from the globular star clusters.

J. NORMAN LOCKYER.

THE THEORY OF SOLUTIONS.

AS some recent *viva voce* remarks of mine have received an interpretation more wide than I intended, I shall be glad to be allowed to explain that when (now several years ago) I became acquainted with the work of van t' Hoff I was soon convinced of the great importance of the advances due to him and his followers. The subject has been prejudiced by a good deal of careless phraseology, and this is probably the reason why some distinguished physicists and chemists have refused their adhesion. It must be admitted, further, that the arguments of van t' Hoff are often insufficiently set out, and

[1] NATURE, November 28, 1895. [2] *Ibid.*, June 4, 1896.

are accordingly difficult to follow. Perhaps this remark applies especially to his treatment of the central theorem, viz. the identification of the osmotic pressure of a dissolved gas with the pressure which would be exercised by the gas alone if it occupied the same total volume in the absence of the solvent. From this follows the formal extension of Avogadro's law to the osmotic pressure of dissolved gases, and thence by a natural hypothesis to the osmotic pressure of other dissolved substances, even although they may not be capable of existing in the gaseous condition. If I suggest a somewhat modified treatment, it is not that I see any unsoundness in van t' Hoff's argument, but because of the importance of regarding a matter of this kind from various points of view.

Let us suppose that we have to deal with an involatile liquid solvent, and that its volume, at the constant temperature of our operations, is unaltered by the dissolved gas—a question to which we shall return. We start with a volume v of gas under pressure p_0, and with a volume V of liquid just sufficient to dissolve the gas under the same pressure, and we propose to find what amount of work (positive or negative) must be done in order to bring the gas into solution reversibly. If we bring the gas at pressure p_0 into contact with the liquid, solution takes place irreversibly, but this difficulty may be overcome by a method which I employed for a similar purpose many years ago.[1] We begin by expanding the gas until its rarity is such that no sensible dissipation of energy occurs when contact with the liquid is established. The gas is then compressed and solution progresses under rising pressure until just as the gas disappears the pressure rises to p_0. The operations are to be conducted at constant temperature, and so slowly that the condition never deviates sensibly from that of equilibrium. The process is accordingly reversible.

In order to calculate the amount of work involved in accordance with the laws of Boyle and Henry, we may conveniently imagine the liquid and gas to be confined under a piston in a cylinder of unit cross-section. During the first stage contact is prevented by a partition inserted at the surface of the liquid. If the distance of the piston from this surface be x, we have initially $x=v$. At any stage of the expansion (x) the pressure p is given by $p=p_0v/x$, and the work gained during the expansion is represented by

$$p_0v\int_v^x \frac{dx}{x} = p_0v\log\frac{x}{v},$$

x being a very large multiple of v. During the condensation, after the partition has been removed, the pressure upon the piston in a given position x is less than before. For the gas which was previously confined to the space x is now partly in solution. If s denote the solubility, the available volume is practically increased in the ratio $x : x + s\mathrm{V}$, so that the pressure in position x is now given by

$$p = p_0v/(x + s\mathrm{V}),$$

and the work required to be done during the compression is

$$p_0v\int_0^x \frac{dx}{x+s\mathrm{V}} = p_0v\log\frac{x+s\mathrm{V}}{s\mathrm{V}}.$$

On the whole the work lost during the double operation is

$$p_0v\left\{\log\frac{x+s\mathrm{V}}{x} + \log\frac{v}{s\mathrm{V}}\right\},$$

and of this the first part must be omitted, as x is indefinitely great. As regards the second part, we see that it is zero, since by supposition the quantity of liquid is such as to be just capable of dissolving the gas, so that $s\mathrm{V}=v$. The conclusion then is that, upon the whole, there is no gain or loss of work in passing reversibly from the initial to the final state of things.

The remainder of the cycle, in which the gas is removed from solution and restored to its original state, may now be effected by the osmotic process of van t' Hoff.[1] For this purpose one "semi-permeable membrane," permeable to gas but not to liquid, is introduced just under the piston which rests at the surface of the liquid. A second, permeable to liquid but not to gas, is substituted as a piston for the bottom of the cylinder, and may be backed upon its lower side by pure solvent. By suitable proportional motions of the two pistons, the upper one being raised through the space v, and the lower through the space V, the gas may be expelled, the pressure of the gas retaining the constant value p_0, and the liquid (which has not yet been expelled) retaining a constant strength, and therefore a constant osmotic pressure P. When the expulsion is complete, the work done upon the lower piston is PV, and that recovered from the gas is p_0v, upon the whole $\mathrm{PV}-p_0v$. Since this process, as well as the first, is reversible, and since the whole cycle has been conducted at constant temperature, it follows from the *second* law of thermo-dynamics that no work is lost or gained during the cycle, or that

$$\mathrm{PV} = p_0v.$$

The osmotic pressure P is thus determined, and it is evident that its value is that of the pressure which the gas, as a gas, would exert in space V.

The objection may perhaps be taken that the assumption of unaltered volume of the liquid as the gas dissolves in it unduly limits the application of the argument. It is true that when finite pressures are in question, an expansion (or contraction) of the liquid would complicate the results; but we are concerned only, or at any rate primarily, with the osmotic pressure of *dilute* solutions. In this case the complications spoken of relate only to the second order of small quantities, and in our theory are accordingly to be dismissed.

January 8. RAYLEIGH.

THE BOG-SLIDE OF KNOCKNAGEEHA, IN THE COUNTY OF KERRY.

AT about three a.m. on Monday, December 28, 1896, a catastrophe occurred some twelve miles north-east of Killarney, of which mention has been already made in these columns (NATURE, vol. lv. p. 205). A bog gave way at its lower edge, and precipitated itself as a black peaty flood into the valley of the Ownacree River. In the upper part of its course it unfortunately overwhelmed the cottage of Cornelius Donnelly, carrying away the structure and its eight occupants. Five of the bodies were recovered, with considerable difficulty, by January 3, when the mass had come practically to a standstill. In the lower part of its course, it flooded a number of farm-lands upon the slopes of the valley, and seriously threatened the cottage of Jeremiah Lyne, rising some five feet against its wall. Even at the junction of the Ownacree and the Flesk, one of the great feeders of the Lower Lake of Killarney, the banks were smeared over with a peaty mud, ten miles from the point of origin of the bog-slide; while a quantity of the material was carried another nine miles west into the Lower Lake itself.

While the first accounts of the disaster were naturally exaggerated, and even contradictory, coming as they did from places on opposite sides of the peaty watershed, an inspection of the area leaves no doubt as to the magnitude of the bog-slide. Such phenomena are not unknown in Ireland, one being recorded from the County of Galway in 1745, and another

[1] *Phil. Mag.*, vol. xxvi. p. 88, 1888.

having been reported on by Sir R. Griffith in 1821 ("Report Relative to the Moving Bog of Kilmaleady in the King's County," *Journ. Roy. Dublin Soc.*, vol. i.). In the latter case, 150 acres became covered with the products to a depth of eight to ten feet, and the flow extended from the edge of the bog one and a half miles down a valley. Probably in all cases such flows are merely a rapid extension of those "creeping" processes which produce rifts and areas of subsidence in bogs formed upon a slope.

The scene of the present bog-slide lies among Carboniferous rocks, and is included in Sheet 174 of the 1-inch Ordnance Map of Ireland (Fig. 1). A perfectly straight road runs N.N.W. from Shinnagh House, which is near the railway; at the cottages of Lisheen a branch runs west, meeting four other roads in the grass-grown quarries of Carraundulkeen. (I use the spelling of the Ordnance Survey throughout.) The bog in which the slip occurred lies between the road from Lisheen and that running almost north from the quarries, which is locally known as the Kingwilliamstown road. It is a brown almost level upland, a mile across, mainly in the townland of Knocknageeha, and is bounded on the north and south by enclosed and cultivated hills, which rise from 780 feet to 847 feet above the sea. The highest point recorded in the bog is 776 feet, and there is a fall of 1 in 38 between this and the bridge between the quarries. The streams on this side flow to the west coast, while the east side of the bog drains direct into the Blackwater.

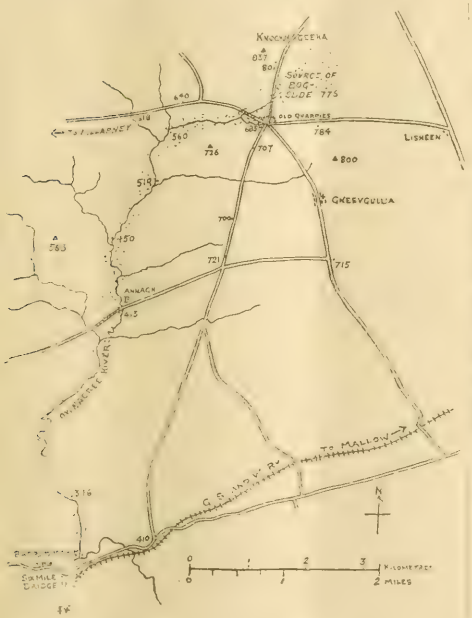

FIG. 1.—Sketch-map showing the site of the Bog-slide, from the maps of the Ordnance Survey. Heights in feet. The course of the flow is indicated by the dotted area.

Several deep peat-cuts existed in the bog, perpendicular to the direction of its subsequent flow, and these have the appearance of rifts or "faults" at a distance. But the lost portion seems to have oozed out from below a large area of the superficial peat, lowering the surface into a series of hummocky and very irregular steps. At the same time, great masses of the surface, with tufts of grass adhering to them, were floated down and hurried into the valley, looking, as one man told me, "as large as houses."

The flow appears to have been rapid and silent, though the noise of the storm which raged through Sunday night kept many of the cottagers awake. Even within a few hundred yards of Donnelly's house, no suspicion of the fate of the unhappy family was raised, until dawn revealed the black flood tossing, and still hurrying down the valley. A young peasant, living close to the edge of the flow, told me that he was roused only by the bellowing of his cow; in another case, a man went at about 4 a.m. to a point three miles down the valley to remove two calves, which he intended to drive into Killarney. He was then almost overtaken by the rise of the peat-flood at Annagh Bridge. I conclude, therefore, that no unusual sound or movement of the earth occurred, such as might have warned him of the coming danger.

FIG. 2.—Broken roadway, with meadows submerged by the peat-flow, at Annagh Bridge. Foreground of heaped-up peat-mud and bog-timber. Lyne's cottage in the distance.

The full flood first attacked the Kingwilliamstown road, on the east side of which the bog abutted. It filled up the hollow, climbed the embankment, and fell over the western side like a very fluid lava-flow. The guiding-line here was the course of the streamlet that drained the bog into the Ownacree River. Probably the road itself has been carried away beneath the thick mass now covering its site, and communication with the north is likely to remain cut off for some weeks. On January 3, movement had ceased at this point, but the embankment on which the road runs alone prevented a further downrush.

Donnelly's cottage stood on the west side of this road, and was totally swept away. Its thatched roof was seen floating for a time, but the house is said to have been built of loose stones, and rapidly succumbed. The bodies recovered were found at various points in the first four miles of the flow.

The Royal Dublin Society have appointed a Commission, consisting of Prof. Sollas, F.R.S., and Messrs. De Lap, A. F. Dixon, and R. Lloyd Praeger, who may be trusted to give us an accurate survey of the flow; the

present paper will therefore be concerned with its broader geological aspects. Viewed from any of the neighbouring spurs, the valley of the Ownacree (the "Quagmire River" of the Ordnance Survey) now seems occupied by a black flood, winding with the course of the original stream. Here and there lake-like expansions occur, with pools of water on their surface; and, lower down the valley, the stream asserts itself, and is now cutting out a channel through the débris, or, rather, is washing out its original course. Without an intimate acquaintance with the country, it is difficult to know what changes have occurred in the form of the true valley-floor; but the local constabulary assert (*Freeman's Journal*, January 2, 1897) that a considerable deepening of the valley has resulted in places from the scouring action of the flow. This obviously applies only to the first two miles or so below the quarries, where the stream originally ran over a flank of the great Annagh bog. At and below Annagh Bridge no trace of any deepening is to be seen; the torrent is merely washing its way clean again, and revealing the original boulders on its floor.

To return to details, the passage of the flow across the western road, between Quarry Lodge and the older quarries, resulted in the filling up of a limestone-quarry and the destruction of the embankment of the road, together with its double hedges. Judging by the state of things at Annagh Bridge, the upper bridge may perhaps be found also standing, when the peat-flood can be cleared away. The destruction here is, however, considerable, and the oozing of the material through the hedges reminds one of the behaviour of some of the thin lava-sheets of Hawaii. Great stems and roots of timber, formerly buried in the upper bog, have been floated down, and stick up fantastically, like arms waving from the flood.

The main road to Killarney is thus effectually breached; and a still more striking scene occurs on the parallel road at Annagh Bridge (Fig. 2). Here the floor of the valley was flat for nearly half a mile west of the bridge, and was divided into a number of fields. The peat has covered the whole of these, and climbed, as has been said, against the wall of Lyne's cottage. The road is broken into sections and seems utterly destroyed; and bog-timber, which is abundant in this district, juts out everywhere above the slime. The peat has left traces on the top of the buttresses of the bridge, six feet above the present level of the water; and movements were noticed here in the subsiding flow a week after the catastrophe.

After this wild scene, the valley narrows, and the black borders to the stream show the height to which the flood first rose; every boulder has a bank of débris behind it, and islets of peat, bog-timber, and grassy tussocks have risen in the middle of the stream. The piers of Six-Mile Bridge, close to Barraduff, six miles from the original bog, are still clogged with timber, and show peat-patches a good five feet above the stream. Even travellers by rail can trace from this point downwards the black deposits on the banks of the Ownacree, down to the viaduct before Headford Junction.

As to the origin of the bog-slide, it must be compared, as already hinted, with the phenomena of surface-creep, which are strikingly illustrated by the stone rivers of the Falkland Isles and the constantly occurring landslides of the taluses of Tyrol. The ridging of soils upon steep hillsides is a well-known and milder form of this sliding motion; and a field laid out upon a slope, in an even moderately rainy climate, may be considered as being always added to at the upper end, and carried away down-hill at the lower. In peat-bogs, the water finds its way out in numerous channels into the main stream of some neighbouring valley; and the banks of these channels are always in a state of flux. During stormy weather, the black saturated lower layers of the bog are washed out in far larger quantity than the brown and drier upper layers. Rifts and signs of movement in the latter will then readily occur.

As Sir R. Griffith pointed out in 1821, there is little cohesion between the water-logged lower layers and the impermeable clay or other material which underlies the whole, and which allows, in the first instance, of the accumulation of the bog. The moving bog in the King's County was accounted for by the occurrence of a dry season, during which extraordinary cuttings were made, giving a face of thirty feet. The pulpy lower layers were thus reached, and were set free, carrying away the upper masses on their surface. The process is analogous to that which forms caverns in many lava-flows, the fluid lower portion becoming liberated and rushing out from under the upper part.

Similarly, the deep cutting of the bog of Knocknageeha may have been injudicious in so wet an area. It is possible that official inspection is required in these matters, as in more elaborate quarrying operations; and the loss of life in the present instance makes a consideration of the condition of other bogs at least desirable. But the immediate cause of the flow seems to have been the heavy rainfall of December 1896, which raised the level of the water in the workings and the level of saturation in the bog. Even in broad daylight it would have been impossible to check the movement, when once the Kingwilliamstown road had been overpowered. The slope on which the bog moved, making in the first mile an approximate allowance for the original thickness of the peat in Knocknageeha, falls about 120 feet in the first mile, 100 feet in the second, 95 feet in the third, and 45 feet in the fourth. The fall of the valley-floor as far as Annagh Bridge is thus about one hundred feet per mile, decreasing rapidly before the bridge; and it may be remembered, for future guidance, that this fall is sufficient to allow of a bog-slide of truly catastrophic character.

GRENVILLE A. J. COLE.

NOTES.

IT is stated that Sir Joseph Lister, on being raised to the peerage, has selected the title of Lord Lister.

LORD KELVIN and Prof. Simon Newcomb have been elected honorary members of the St. Petersburg Academy of Sciences, and Lord Rayleigh has been elected a corresponding member.

THE Geological Society of London will this year award its medals and funds as follows:—The Wollaston Medal to W. H. Hudleston, F.R.S.; the Murchison Medal and part of the Fund to Horace B. Woodward, F.R.S.; the Lyell Medal and part of the Fund to Dr. G. J. Hinde, F.R.S.; the Bigsby Medal to Clement Reid; the proceeds of the Wollaston Fund to F. A. Bather; the balance of the proceeds of the Murchison Fund to S. S. Buckman; the balance of the proceeds of the Lyell Fund to W. J. Lewis Abbott and J. Lomas.

ANOTHER instance of the interest which the German Government takes in the advancement of science is afforded by the fact that an item in the Prussian estimates is a vote of 50,000 marks to the Ministry of Public Instruction for investigations with the Röntgen rays. The vote (says the Berlin correspondent of the *Times*) is justified by a reference to the importance which the new invention has been shown to possess in the spheres of physics, anatomy, physiology, zoology, botany, and kindred sciences. The object of the grant is to enable institutes and certain men of science to procure the necessary apparatus, and to defray the expense of exhaustive experiments.

THE Royal Academy of Sciences of Turin announces that the term for competition for scientific works and discoveries made in the four previous years 1893-96, to which only Italian authors

and inventors were entitled, was closed on December 31, 1896. The Academy now gives notice that the new term for competition for the eleventh Bressa Prize, to which scientific men and inventors of all nations will be admitted, has begun. A prize will, therefore, be awarded to the scientific author or inventor, whatever his nationality, who during the years 1895-98, "according to the judgment of the Royal Academy of Sciences of Turin, will have made the most important and useful discovery, or published the most valuable work on physical and experimental science, natural history, mathematics, chemistry, physiology, and pathology, as well as geology, history, geography, and statistics." The term will be closed at the end of December 1898. The sum fixed for the prize, deducting income tax, will be of 9600 francs. Competitions, which must be in print, must be sent in within the above-stated time, accompanied by a letter to the President of the Academy. Unsuccessful competitive works are not returned. None of the national members, resident or non-resident, of the Turin Academy can obtain the prize. The prize may, however, be awarded to a non-competitor if he is considered the most worthy to receive it.

WE have it on the authority of the *Times* correspondent at Monte Video, that the report is fully confirmed that Prof. Giuseppe Sanarelli, who is director of the Uruguayan National Institute of Experimental Hygiene, has discovered the bacillus of yellow fever, and will shortly publish the result of his experiments. He has already reported his discovery to the Academy of Medicine in Rome.

IN consequence of the danger for Russia caused by the spread of the plague in India, the Russian Government has decided to appoint a special commission, under the presidency of the chief of the sanitary department, Dr. Rogozin, whose task will be to decide upon the necessary measures of precaution and the means for carrying them out promptly. We learn from the *Times* correspondent at Cairo, that Rogers Pasha, Director-General of the Sanitary Department, and Dr. Bittar, Government bacteriologist, are commissioned to study the epidemic plague in Bombay and the best measures for safeguarding Egypt against its introduction, the danger lying especially in the infection of the Mecca pilgrims.

THE Peninsular and Oriental Company's steamer *Nubia* arrived in Plymouth Sound, from Calcutta, on Saturday last, with a detachment of the North Lancashire Regiment, and it was reported that several cases of cholera had occurred among the troops a few days after the vessel had touched at Port Said. Seven deaths have taken place, and eight cases are now under treatment in the hospital ship *Pique*; but there is no suspicion that the disease will extend further. The origin of the outbreak of the disease on board the ship is at present doubtful, but medical officers of the Local Government Board are actively engaged in investigating it. Dr. Bulstrode has given it as his opinion that there was no fault in the water supply of the ship. It is suggested that fruit consumed at Port Said was the source of the disease, but little support can be found for this theory. As the outbreak occurred among men of a regiment at present stationed at Ceylon, possibly it originated at Colombo, where there was a sharp attack of cholera shortly before Christmas.

MR. HORATIO HALE, of Canada, the well-known anthropologist, died on December 29. He was vice-president of the American Association for the Advancement of Science, for the Anthropological Section in 1886, at the third Buffalo meeting. We regret also to record the deaths of Johann August Streng, the mineralogist, at Giessen; Dr. John William Stubbs, Senior Fellow of Trinity College, Dublin; Dr. P. Binet, Deputy Professor of Therapeutics in the University of Geneva, and author of numerous researches on the action of drugs, aged forty-one; Dr. Ferdinand Morawitz, founder of the Entomological Society of St. Petersburg; and Dr. Modest Galanin, editor of the St. Petersburg *Journal of Public Hygiene*.

THE large male Patagonian Sea-lion (*Otaria jubata*), which has been one of the great attractions in the Zoological Society's Gardens since its arrival in 1866, having died of old age, its place has been temporarily filled by a small female of the Cape Sea-lion (*Otaria pusilla*). But measures are being taken, we believe, to obtain another representative of one of the larger species of this group.

DURING his recent adventurous journey across British New Guinea (see *Geogr. Journ.*, 1897, p. 93), Sir William MacGregor discovered a fine new Bird of Paradise on the heights of Mount Scratchley. An example of this bird has arrived in England to be figured in the next number of the *Ibis*, and will be exhibited by Mr. Sclater at the next meeting of the British Ornithologists' Club on the 20th inst.

THERE are now in this country, says the *British Trade Journal*, a number of Japanese experts appointed by their Government to study the iron and steel making processes and plant of the leading European and American works. They will leave shortly for the continent, to examine the principal iron and steel centres of France, Belgium, and Germany, and probably of Austria and Sweden, returning to this country to visit South Wales prior to their departure for Japan *viâ* the United States. At the end of their tour they are to decide upon the processes and plant best adapted for the production of steel and iron from Japanese coal and ore, the Japanese Government having voted 500,000*l.* for the establishment of works for this purpose near Shimonoseki. The building of these is to begin next autumn, and they will, when finished, have an output of 100,000 tons a year.

ON Tuesday next, January 19, Prof. Augustus D. Waller, F.R.S., will deliver the first of a course of twelve lectures on "Animal Electricity," at the Royal Institution. On Thursday, January 21, Prof. Henry A. Miers, F.R.S., will begin a course of three lectures on "Some Secrets of Crystals." The Friday evening meetings of the members will commence on January 22, when Prof. Dewar will deliver a lecture on "Properties of Liquid Oxygen." Prof. J. C. Bose will deliver his discourse, on "The Polarisation of the Electric Ray," on Friday evening, January 29, and not on February 5, as previously announced.

THE second series of the Sunday Lecture Society's programme commences on January 17, when Prof. Norman Collie, F.R.S., will lecture on "The Mountains of Britain." Among the other lecturers who will discourse on Sunday afternoons at St. George's Hall, Langham Place, between now and the end of of next month, are Prof. L. C. Miall, F.R.S., on "Life on the Surface of Water"; Dr. C. W. Kimmins, on "Ancient and Modern Views of Fire"; and Mr. Arthur W. Clayden, upon "The Light of the Stars."

NO excuse is needed in again directing attention to the appeal which has been made for funds to defend the public right of access to the Giant's Causeway, County Antrim, Ireland. It seems almost incredible that an attempt should be made to enclose such a wonderful natural formation as the Giant's Causeway, which has been open to the public from time immemorial, and is annually visited by about 80,000 persons. A few persons have, however, lately formed themselves into the Giant's Causeway Company, Limited, and leased from the owners the soil over which the Causeway is approached, claiming the right to close public access to it. The Company has

instituted proceedings in the Court of Chancery to establish their claim, and restrain the defendants (members of the public who recently visited the Causeway) from trespassing on the Company's ground. The costs of defending the public rights may amount to 400*l.* or more, and this has to be raised by subscription. We hope and believe that when the general public come to know how matters stand, and that prompt and decisive action is necessary, they will rally to support the Defence Committee, and contribute to defray the expense involved in defending the suit. Subscriptions are earnestly appealed for, and may be forwarded to Sir William M'Cammond, Town Hall, Belfast, Treasurer; or, Seaton F. Milligan, Bank Buildings, Belfast, Hon. Sec. The National Footpath Preservation Society has prepared a leaflet containing a tracing of the Causeway and neighbourhood from the 6-inch Ordnance Map, and views of the basaltic formations. These illustrations, with the text which accompanies them, should be successful in gaining subscriptions for the righteous cause which the Defence Committee has in hand.

THE epidemic of bubonic plague at Bombay has assumed very alarming form. According to the official returns there have been up to the present 2850 cases of plague and 2028 deaths. The mortality for the past week from all diseases was 1711. The exodus from Bombay has now amounted to between 100,000 and 150,000 persons. The plague is also rapidly increasing at Karachi, where, up to January 10, there had been 220 cases and as many as 214 deaths. In connection with the question of the spread of plague, some remarkable information is contained in a lecture delivered by Dr. James Cantlie before the Epidemiological Society, and printed in the *Lancet*. Rats appear to be particularly susceptible to plague. There was a great mortality amongst rats in the Hong-Kong epidemic, and in Canton the rats entirely disappeared from districts of the city where the diseases had lasted for some time; as many as 22,000 dead rats were collected in a few weeks. But more remarkable than this tremendous mortality is the fact that a month before the plague broke out in Bombay, it was known that the rats were dying in thousands. The rat, therefore, seems to be affected before the human being; and the fact of dead rats being found about a house during the plague epidemic is, Dr. Cantlie thinks, a true warning that the inmates of the house will, in all probability, be attacked. Not only rats, but pigs, dogs, snakes, jackals, and pigeons are affected by a fatal malady whilst plague is epidemic among human beings. What Dr. Cantlie concludes from the study of infection of animals is: (1) that the rat is the animal most liable to be attacked by plague; (2) that rats suffering from, or dead from plague may infect other animals, such as snakes and jackals, who consume them; (3) that rats are always affected by a disease similar to plague at the same time man suffers; (4) that the rat may infect man, but the means of conveying the contagium is not known. As to the high mortality of rats before the plague, it seems doubtful whether rats are really infected before human beings, or whether only the incubation period is shorter in them than in man.

TO our previous brief note (p. 159) on Mr. J. E. S. Moore's work at Lake Tanganyika, where he spent some months in the study of the fish and fresh-water medusæ of the lake, we now add the following particulars from the *Central African Gazette*, published at Zomba:—"Mr. Moore spent most of his time at the station of Nyamkolo, on the southern shore of Lake Tanganyika, and from there he made various journeys by boat and by land, travelling up the west coast as far as Muliro's, and up the east shore of the lake as far as the Belgian station Karema. He also crossed over from the south end of Tanganyika to the mountains overlooking the north-western end of Lake Rukwa, and saw this lake in the distance. It is a curious fact that although five or six Europeans have seen Lake Rukwa, only two have been able to reach its waters. Dr. Cross in 1889 made his way through the swamp and reeds near the southern end of the lake, and Mr. Nutt in 1895 just reached the shore at the south-western side. Mr. Moore verified the report, which travellers on Tanganyika have heard from time to time, that there is a large fish in the lake which rushes at the paddles of a canoe passing through the water. He actually say this take place. He also discovered a large electric fish which gives a severe shock on being touched. Tanganyika, indeed, appears to be full of fish. By trailing a line with an artificial minnow behind the boat, Mr. Moore caught enormous numbers of fish, some of them up to sixty pounds in weight—bright clean fish with silvery scales. The heaviest fish which was seen in the lake weighed over ninety pounds; this was a sort of mud fish. Sponges were also discovered in Tanganyika, which, though of no great size, were undoubtedly real sponges. On the east side of the lake, in a bay where the striped leech was very common, Mr. Moore found a small fish about the size of a small minnow, whose back was striped in imitation of the leech, and this seemed to protect it against the raids of the kingfishers which, while constantly picking up other small fish, avoided this particular one."

IN the current number of the *Astrophysical Journal* (December 1896), Mr. L. E. Jewell gives us the results of his investigation of the relative quantities of aqueous vapour in the atmosphere determined by means of the absorption lines in the spectrum. The method of observation was to estimate the intensity of the water vapour lines in terms of the solar lines most nearly equal to them in intensity, and close enough to render the comparisons exact. The work was found to be considerably facilitated by making a scale, the use of which eliminated several otherwise necessary computations and reductions. Among some of the results may be mentioned the following:—The intensities for the summer months were much greater than for the winter months. A comparison of the curves (deduced from monthly means) representing these intensities, and one representing oxygen, shows that water vapour is very differently distributed in our atmosphere from oxygen, and is also greatly different at different seasons. The curves of intensity indicated "a remarkable difference between the conditions prevailing during cold waves and very warm humid weather." Mr. Jewell is of opinion that observations made with small spectroscopes having insufficient dispersion to easily see the various lines distinctly, are worse than useless for weather forecasting, as the region of the rain band contains many solar lines which cannot be distinguished from water vapour lines without good definition and considerable dispersion. With sufficient dispersion, however, the study of the distribution of water vapour in the atmosphere is of great value, but hardly sufficient to justify the use of spectroscopes at most meteorological stations.

WRITING in the *Monthly Weather Review*, Prof. Cleveland Abbe says:—Many persons still fail to realise the fact that the weather proverbs which pass down from generation to generation as unquestioned as are the nursery stories, belong to what may be properly called mythology. Like the myths and legends of ancient times, they may, possibly, have had some slight basis of fact; they may possibly have applied satisfactorily to some far-off period and some far-distant land, or to one special occasion, but do not, necessarily, hold good to-day and in our own country. At a recent meeting of the Meteorological Society of France, the members discussed the popular proverb: "When it rains on St. Medard's day it will rain for forty days unless fine weather returns on

the day of St. Bernabe." M. Teisserenc de Bort showed that M. Lancaster, who, several years ago, examined this question, found no results tending to verify this saying to predict in advance a rainy period; thus in examining the data collected from 1863 to 1896, he finds that in the first days of June the rain is, on the average, a little more abundant, and diminishes towards the end of that month. He himself had also studied the records, but could not find any systematic grouping of the days of rain around the day of St. Medard. M. Renou said that M. Elie de Beaumon has called attention to the fact that the proverb relative to St. Medard dates from the middle ages, and that since then the order of the saints' days in the calendar has been changed, and that now the day of St. Gervais is the one to which the proverb should be applied. M. de Beaumont, therefore, examined the question of the grouping of days of rain according to the new date, but did not find any verification of the proverb.

THE *Monthly Weather Review* (Washington) for September last contains, among various other interesting notes, one upon the first attempt to measure wind force. Prof. Marvin points out that Sir Isaac Newton in his boyhood made a rough determination of the force of a great gale which occurred on September 3, 1658, by jumping first in the direction in which the wind blew, and then in opposition to the wind, and afterwards measuring the length of the leap in both directions. An account of this will be found in Sir David Brewster's "Memoir" of Sir Isaac Newton. The first piece of apparatus applied to the measurement of the wind was probably the pendulous plate anemometer introduced by the Royal Society on the recommendation of Sir Christopher Wren and others, about 1665. This instrument gave a measurement of the effect of moving air on a resisting plate. The question of the measurement of the pressure or velocity of the wind by anemometers is still in a condition far from satisfactory, and the recent annual reports of the Meteorological Council show that the subject is still engaging the attention of that body.

MR. G. H. KNIBBS, Lecturer on Surveying in the University of Sydney, has communicated to the Royal Society of New South Wales, a note on recent determinations of the viscosity of water by the efflux method. From his tables it would appear that, for temperatures from 0° to 50° C., the relative fluidity has been ascertained to within 1 per cent., but that from 50° to 100° C. the uncertainty increases to 5 per cent. This large uncertainty is apparently not explained by possible errors of observation either of temperatures, efflux times, or of the dimensions of the apparatus. These conclusions are derived from a comparison of the observations of Poiseuille, Graham, Rosenkranz, Shotte, Traube, Noack, and Thorpe and Rodger.

THE importance of the study of the ceremonies of the Australians can scarcely be over-estimated, and it is with pleasure that we draw attention to the recent work in this direction done by R. H. Mathews, who as a professional surveyor has good opportunities for study, of which we are glad to find he makes so excellent a use. In a paper contributed to the Queensland Branch of the Royal Geographical Society of Australasia (vol. x. p. 18, pl. 1), he dealt with the Kamilaroi Class System of the Australian aborigines. The initiation or Bora ceremonies of the Kamilaroi tribes were described in the *Journal of the Anthropological Institute* (vols. xxiv., xxv. pp. 411, 318), and in the *Journ. Roy. Soc. N.S.W.* (vol. xxviii. p. 103); the analogous Burbung ceremonies of the Wiradthuri tribes in the *Journ. Anth. Inst.* (vol. xxv. p. 295); and the similar Bunan ceremony of the south-east coast of New South Wales in *The American Anthropologist* (vol. ix. p. 327). The careful descriptions are supplemented by plans of the grounds where the ceremonies took place, and sketches of the various animals and designs that are carved on neighbouring trees, or cut on the surface of the ground. Mr. Mathews has also published several accounts of the rock paintings and carvings of the Australian aborigines, and we would refer the reader to the following papers: *Journ. Roy. Soc. N.S.W.* (vol. xxvii. p. 353) (for the one in vol. xxix. he obtained the Society's medal), *Proc. Roy. Geogr. Soc. Aust. Queensland Branch* (vol. x. p. 46), *Proc. Roy. Soc. Victoria* (vol. vii. n.s. p. 143), *The American Anthropologist* (vol. viii. p. 268), *Journ. Anth. Inst.* (vol. xxv. p. 145). It is evident that Mr. Mathews has taken a great deal of pains to be accurate, and his training has been valuable for this special kind of work. All the drawings are necessarily reproduced on a very small scale; but it is to be hoped that the original drawings will be preserved in some convenient public institution, where they will be available for future students. We hope that he will be encouraged to continue his labours, and trust that he and others who have the opportunity will find out, *from the natives themselves*, the significance of all the designs and patterns which they come across. With a few more workers like Mr. Mathews, the reproach of the neglect of Australian anthropology would largely be taken away.

MR. C. H. TYLER TOWNSHEND has recently contributed to the *Transactions* of the Texas Academy of Science an essay on the Bio-geography of Mexico, Texas, New Mexico, and Arizona. In this, he criticises Dr. Merriam's division of the life-zones of Eastern North America, "which he has had constant and abundant opportunities of studying during the past five years." Mr. Townshend recognises seven zones of altitude in the district to which he has devoted his attention, and, commencing at the highest, calls them respectively the Arctic, Hudsonian, Canadian, Arid-Transition, Upper-Sonoran, Lower-Sonoran, and Tropical Zones. These he proceeds to define, chiefly by reference to their different and characteristic forms of vegetation.

WE have received Nos. 2 and 3 of the eighteenth volume of *Notes from the Leyden Museum*, which were published on December 24 last. Besides many entomological and several conchological papers, the publication contains an article by Dr. J. Büttikofer on the birds of Nias, the largest of a long series of islands flanking the west coast of Sumatra, and situated at a distance of about seventy miles from its north-west coast, which has, of late years, been more than once the subject of zoological investigations. Dr. Büttikofer bases his paper on a splendid series of bird-skins collected in this island by Mr. J. Z. Kannegeiter, but takes the opportunity of giving a complete list of the birds of Nias, so far as they are known up to the present time, which are 128 in number. The relationship of this Avifauna is with that of Sumatra, but there are eleven species of birds in Nias which have not been found anywhere else as yet.

AT the Liverpool meeting of the British Association, the Committee for the Study of the Marine Zoology, Botany, and Geology of the Irish Sea presented its fourth and final report, drawn up by Prof. Herdman, a printed copy of which has now reached us. It contains, besides a brief account of the year's work, a complete list of all the species the Committee has recorded from the area. The total number of species included is 2133, and the list comprises all the chief marine subdivisions of the animal kingdom, and also Algæ and Diatomacea. Each name is followed by a reference to the publication of the Liverpool Marine Biology Committee in which the species was recorded or described. The British Association Committee is dissolved, not because the work is finished, but because it was decided that the Association could best render effective help by supporting the Port Erin Biological Station, which is now established and equipped, or by giving grants for special researches.

THE formation of organic bases by plants of the orchid family appears first to have been investigated by M. de Wildemann, who in 1892 observed the presence of an akaloidal product in *Dendrobium nobile, D. Ainsworthii*, and other Orchidaceæ. These researches have now been generalised by Dr. E. de Droog, whose investigations are published in the *Mémoires* of the Royal Academy of Belgium. Of the 104 species of orchids examined, nine are to be considered as producing alkaloids, some in all their parts, the others locally, and the author seems to favour the view that the function of these alkaloids is for defensive purposes. Dr. de Droog's paper is illustrated by a lithographed plate, in which the alkaloids present in the cells of *Dendrobium nobile, Catasetum Hookeri, C. macrocarpum*, and the root of *Phalænopsis Luddemanniana* are coloured red.

M. CAMILLE FLAMMARION has sent us his interesting annual for the present year, and it is a mine of knowledge, both astronomical and meteorological. The information is not presented in too concentrated a form, but varied in places by explanations and summaries, together with excellent illustrations (fifty-six in number). Some of the main points which call for especial notice may be stated as follows. Under eclipses two clear diagrams are given, showing the most favourable points for viewing the two annular and only solar eclipses of the year. In addition to the ephemeris of each planet, charts are given showing their apparent tracts among the stars. For each day of the year the most interesting phenomena to be observed are inserted in calendar form, and diagrams are added showing the positions of the constellations for each month. A list of the minor planets, arranged in order of their perihelia distances, forms an interesting table. Among the *Notices Scientifiques* may be mentioned a chart of the movement of the terrestrial pole from 1890-95, a note on helium, and a brief reference to the recent total solar eclipse, with Dr. Brester's drawing of the corona. Lowell's chart of Mars on a reduced scale, and some planetary drawings, as well as a short summary of the eclipse cycle of fifty-four years, are also inserted. Besides being serviceable to astronomers, this annual should prove a valuable *vade-mecum* to amateurs, as they have at hand all the information for observing, at the right time, the most interesting celestial phenomena.

WE have received from the compiler, Mr. Arthur Mee, an almanac of moderate size for the use of amateur astronomers. The information is arranged in the form of a calendar, and shows the observer, at a glance, the sequence of the more important phenomena that will occur throughout the year. In addition to data referring to the positions of the sun and moon, attention is drawn to the most favourable times for viewing the planets, variable star and satellite phenomena, besides a selection of special clusters and nebulæ most suitable for small apertures. The arrangement of the information is simple and clear, so that this card almanac supplies a really serviceable daily reference sheet to those for whom it is specially intended. There is also a very good reproduction of the moon, taken from a photograph made at the Paris Observatory. One cannot help mentioning that as the almanac is intended for actual observers, the type of both figures and letters will most probably be found too small to be read in any but very good light. As amateurs would be very likely to consult this sheet when observing, it would not be an easy matter to read it by means of the light of an ordinary observatory lamp. It seems to us, however, that the utility of the sheet would be increased if larger and clearer type were in future used. The almanac, nevertheless, contains just that information which an amateur wishes to have at hand, and it should therefore be found to supply a real want.

MR. C. A. BARBER shows, in *Science Progress*, that the present condition of the sugar industry is peculiarly a matter of British interest. The depressed condition of the British colonies engaged in growing the sugar-cane is due to various causes; chief among these are the competition of European-grown beet and the various diseases at present attacking the canes. In his paper, Mr. Barber deals more especially with the first of these causes. The paper on the cell and some of its constituent structures, read at the Liverpool meeting of the British Association by Prof. J. B. Farmer, is printed in full in the same number of *Science Progress*. Dr. John Beddoe continues his paper on "Selection in Man." From the facts he adduces it seems that dark-complexioned men have a bias towards sedentary and indoor employments, while a certain number of the blond type prefer the outdoor employments connected with the land or with the care of animals. The statistics he gives support the conclusion that, in this country, more criminals than honest men are of dark complexion. Other contributions are:—"The Glossopteris Flora," by Mr. A. C. Seward; "Condensation and Critical Phenomena," by Prof. J. P. Kuenen; "The Origin of Lakes, by Mr. J. E. Marr, F.R.S.; and "The Causes of Variation," by Mr. H. M. Vernon.

FROM Prof. E. Cosserat, of Toulouse, and M. F. Cosserat, of Paris, we have received the first part of their memoir "Sur la Theorie de l'Elasticité," in which the principles of the subject are well put forward.

BY the publication of Part v. of the "Bibliography of American Economic Entomology," the task of bringing together the more important writings of Government and State Entomologists, and other contributions to American economic entomology, is completed up to the year 1888. Efforts will be made to bring the bibliography up to date by publishing occasional supplements. The work is published by the authority of the U.S. Secretary of Agriculture, and the present part of it has been prepared by Mr. S. Henshaw.

THE additions to the Zoological Society's Gardens during the past week include a Pig-tailed Monkey (*Macacus nemestrinus*, ♂) from Java, presented by Mrs. Baillie; two Leopards (*Felis pardus*, ♂ ♀) from Ceylon, presented by the Hon. Sir Joseph West Ridgeway; a Moluccan Kestrel (*Tinnunculus moluccensis*) from Triton Bay, New Guinea, presented by the Hon. Walter Rothschild; two Roseate Cockatoos (*Cacatua roseicapilla*) from Australia, presented by Mr. Richard J. L. Price; a Yellow-backed Lory (*Lorius flavo-palliatus*) from Batchian, presented by Miss A. M. Elwood; a Derbian Zonure (*Zonurus giganteus*), three Angola Frogs (*Rana angolensis*) from South Africa, presented by Mr. J. E. Matcham; seven Common Squirrels (*Sciurus vulgaris*), British; two Indian Dial Birds (*Copsychus saularis*) from India, purchased; a Bennett's Wallaby (*Macropus bennetti*), a Rufous Rat Kangaroo (*Œpyprymnus rufescens*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE ALGOL VARIABLE + 17° 4367 W DELPHINI.—Prof. E. C. Pickering publishes in the *Astrophysical Journal* for December the ephemeris and light equation of this variable for the present year. No modification is made in the formula of reduction (JD 2412002·500 + 4·8064 E), although the observations indicate a slight change in the period, making the minima occur about fifteen minutes before the computed times. Prof. Pickering adds, however, that by diminishing the period by about two seconds this difference, caused by an inexact knowledge of the light curve when the ephemeris was first computed, would disappear. A set of photometric measurements with the adjacent star + 17° 4368, exceeding four thousand in number, and made by Mr. O. C. Wendell, has given a very accurate

light curve, which Prof. Pickering reproduced in his note. The average deviation between the photometric measurements and the smooth curve amounts to between one or two hundredths of a magnitude. The observations are not, however, quite sufficiently distributed over the whole curve to eliminate all doubt as to its form in some parts. The light curves of U Cephei, β Persei, and U Ophiuchi have also been similarly determined. W Delphini varies 2·71 magnitudes, a variation greater than any other star of the same class. U Cephei comes second, with a variation of 2·44 magnitudes, while those of β Persei and U Ophiuchi are 1·04 and 0·66 respectively.

COMET NOTES.—The comet discovered by Mr. Perrine, on December 8 last year, is gradually diminishing in brightness; but the ephemeris shows that its now southern declination is beginning to diminish. For those wishing to follow the comet further, Dr. F. Ristenpart has computed some parabolic elements from observations made on December 10, 22, and 27, and the ephemeris obtained from these is as follows (*Astr. Nachr.*, No. 3394, Beilage):—

Berlin Midnight.

1897.		R.A. h. m.		Decl. ° ′		Br.
Jan. 11	...	4 2·8	...	−0 53·4	...	0·27
15	...	17·4	...	54·3	...	·22
19	...	30·7	...	47·1	..	·18
23	...	43·1	...	34·9	..	·15
27	...	54·5	...	19·1	...	·12
31	...	5 5·2	...	−0 0·6	...	0·10

The elements are stated to be not very satisfactory, as the calculation of the "mean position" discloses an error of too great a magnitude to be neglected.

The comet, on the other hand, discovered by Mr. Perrine on November 2, is, according to the ephemeris given by Herr Otto Knopf (*Astr. Nachr.*, No. 3394), increasing rapidly in brightness, and by April 5 will be six times brighter than it was at the time of its discovery. The comet, however, will soon be lost in the sun's rays, but on its reappearance will be visible only from southern latitudes, its southern declination rapidly increasing.

THE UNIVERSAL MERIDIAN.—Among many of the subjects referred to at the meeting of the Société Astronomique de France, on December 2 last year, that of the choice of a universal meridian raised considerable discussion. The subject was brought up owing to the proposition made by M. Deville, before the Chambre des Deputés, concerning "the adoption of the meridian of Greenwich by France." M. Bouquet de la Gyre commenced the proceedings by saying that the question was one which touched science as a whole, and that the Academy had not been consulted. He then proceeded to state his opinion, which was to the effect that for theoretical reasons Greenwich should not be adopted as the zero meridian. M. Callandreau, who followed him, took the practical side of the question, and pointed out what progress had already been accomplished in the adoption of the Greenwich meridian. After an able statement of the case by the President, M. Janssen, the question was put to the vote, the great majority adhering to the adoption of the Greenwich meridian. The proceedings of the meeting will be found in the *Bulletin* of the Society for January.

PRIZE SUBJECTS OF THE PARIS ACADEMY OF SCIENCES.

THE following subjects for prizes are announced by the Academy for 1897 and following years; prizes for years other than 1897 are specially indicated. In Geometry, the Grand Prize in the Mathematical Sciences (1898) will be awarded for the best memoir extending the part played in analysis by divergent series; the Bordin Prize (3000 fr.) for a study of the questions relating to the determination, properties, and applications of systems of orthogonal curvilinear coordinates of n variables, indicating particularly the degree of generality of these systems (1898); the Francœur Prize (1000 fr.), and the Poncelet Prize (2000 fr.), for work contributing to the progress of pure or applied mathematics. In Mechanics, the Extraordinary Prize of 6000 fr. is offered for work increasing the efficiency of the French naval forces; a Montyon Prize (700 fr.) for the invention or improvement of instruments useful in agriculture or the mechanical arts; the Plumey Prize (2500 fr.), for improvements in steam navigation; the Fourneyron Prize, for a complete discussion of the motion and stability of bicycles. In Astronomy, the Lalande Prize (540 fr.) will be given for the observation or work most useful to the progress of the science; the Damoiseau Prize (1500 fr.), for calculations connecting the appearances of Halley's comet, taking into account the attraction of Neptune, and giving the exact time of its next appearance in 1910; also, for 1898, for a study of the perturbations of Hyperion, the satellite of Saturn, deducing the mass of Titan; the Valz Prize (460 fr.), for the most interesting astronomical observation made during the year; and the Janssen Prize (for 1898), for the most important discovery in Astronomical Physics.

In Physics, a La Caze Prize (10,000 fr.), in Statistics, a Montyon Prize (500 fr.), and in Chemistry, a La Caze Prize (10,000 fr.), and the Jecker Prize (10,000 fr.) will be awarded in 1897. In Mineralogy and Geology, for the Grand Prize in the Physical Sciences (3000 fr.), question proposed for 1897, "New experiments and studies on the higher parts of mountains, especially experiments bearing on Meteorology and the conditions of life"; for the Bordin Prize (3000 fr.), "Physical, chemical, and zoological studies of the bottom of the seas touching the coast of France"; for the Vaillant Prize (4000 fr.), question for 1898, "To make known and discuss the indications which complete the microscopical study of the sedimentary rocks (especially secondary or tertiary rocks) from the point of view of their genesis and the modifications they have undergone since their deposit in their structure and composition"; the Delesse Prize (1400 fr.), for work in Geology or Mineralogy; and the Fontannes Prize (2000 fr.) in 1899, for the best palæontological publication.

In Botany, the Barbier Prize (2000 fr.) is offered for a discovery of medical value; the Desmazières Prize (1600 fr.), for the best work on Cryptogams published during the year; the Montagne Prizes (1000 fr. and 500 fr.), for important discoveries bearing on the anatomy, physiology, and development of the lower Cryptogams; the De la Fons Melicocq Prize (900 fr.), in 1898, for work on the Botany of the North of France; and the Thore Prize (200 fr.), for the best memoir on the Cellular Cryptogams. In Anatomy and Zoology, the Savigny Prize (975 fr.) will be given in aid of young zoologists who have specially occupied themselves with the study of the Invertebrates of Egypt and Syria; and the Da Gama Machado Prize (1200 fr.), for the best memoirs on the coloured parts of the tegumentary system of animals. In Medicine and Surgery, there is offered a Montyon Prize; a Barbier Prize (2000 fr.); the Bréant Prize (100,000 fr.), for the discovery of a remedy which shall cure Asiatic cholera in the great majority of cases; the Godard Prize (1000 fr.), for the best memoir on the anatomy, physiology, and pathology of the genito-urinary organs; the Serres Prize (7500 fr.), in 1899, for work on General Embryology applied as far as possible to Physiology and Medicine; the Chaussier Prize (10,000 fr.), in 1899, for a work advancing legal or practical Medicine; the Parkin Prize (3400 fr.), for researches on the curative effects of carbon; the Bellion Prize (1400 fr.), for work especially profitable to the public health; the Mege Prize, for an essay on the progress of Medicine; the Dusgate Prize, in 1900, for the best means of preventing premature burial; the Lallemand Prize (1800 fr.), for work on the nervous system; and the Baron Larrey Prize (1000 fr.), for work on Military Hygiene, Medicine, or Surgery.

In Physiology, the Prizes proposed are those of Montyon (700 fr.), La Caze (10,000 fr.), Pourat (1400 fr.), Martin-Damourette (1400 fr.), and Philipeaux (890 fr.), and in Physical Geography, the Gay Prize (2500 fr.).

Of the General Prizes, there will be awarded in 1897, a Montyon Prize for a means of ameliorating an unhealthy trade or occupation; the Cuvier Prize (1500 fr.), for a work on Geology; the Trémont Prize (1100 fr.) and the Gegner Prize (4000 fr.); the Petit D'Ormoy Prize (10,000 fr.), for work in Pure and Applied Mathematics, and in the Natural Sciences; the Tchihatchef Prize (3000 fr.), for work on the less known parts of Asia; the Gaston Plante Prize (3000 fr.), for an important invention in Electricity; and the Cahours Prize (3000 fr.), for assisting young chemists in chemical researches.

Of these prizes those bearing the names of Lalande, La Caze, Delesse, Desmazières, and Tchihatchef, are specially stated to be given without distinction of nationality. All memoirs for this year must be sent to the Academy before June 1.

THE OLD TURKISH INSCRIPTIONS IN MONGOLIA.[1]

ABOUT 170 years ago it became known in Europe that there are, on the Upper Yenisei, inscriptions on stone monuments which are written in some unknown language, and are relics of an unknown population. Various hypotheses were made as to the origin of these inscriptions; but it was only in 1893 that the Copenhagen Professor, Wilhelm Tomsen, succeeded in deciphering them.[2] Although Prof. Tomsen attributes the discovery of these inscriptions to Heikel and Dr. Radloff, who visited the spot—the former in 1890–1891, and the latter in 1891—they were discovered in reality by the late N. M. Yadrintseff, who was sent out in 1889 by the Irkutsk Geographical Society for a journey to Mongolia.[3] Heikel's collection was luxuriously edited by the Finnish-Ougrian Society,[4] and the collection of reproductions made by MM. Radloff and Yadrintseff was published by the Russian Academy of Sciences.[5] However, neither of these three explorers succeeded in reading the inscriptions, and it was only Prof. Tomsen who, taking advantage of the names of rulers, which were written in Chinese characters, and stood by the runic inscriptions, found the cue for reading the mysterious writings. It became thus known that the inscriptions belonged to a Turkish stem which formerly inhabited the upper parts of the Yenisei and the Orkhon. The cue having been discovered, Prof. Radloff set at once to decipher and to translate the inscriptions—a task which involved very great difficulties at the outset, as the vowels were not written in this alphabet; but with all that, Dr. Radloff succeeded in finding out the meaning of the inscriptions and in translating them, and his researches are now embodied in a work issued by the Russian Academy of Sciences.[6] In this work Dr. Radloff analyses, first, the alphabet of the old Turkish monuments, and, next, the Chinese monuments on Lake Kosho-tsaidam; he then gives an eighty-page long list of words; the translation of the Chinese Kosho-tsaidam inscriptions, by Prof. Vasilieff; and the translations of the inscriptions found in different places of Mongolia and on the Yenisei, on both Chinese and Russian territory, followed by a study on the morphology of the old Turkish dialect. Thirty inscriptions in all have been deciphered; they are written phonetically, in vertical columns following each other from the right to the left. The letters are angular; they contain only four vowels and thirty-four consonants—different consonants being used in the words which contain guttural vowels, and in those words which have palatal vowels.

The Chinese inscription at Kosho-tsaidam was written on a monument erected in 732, to honour the Turkish ruler Kyulteghin, under the Chinese Emperor Kai-yuang, who reigned A.D. 713 to 742. A people named "Turk" is mentioned in it, and the monument was erected on that people's territory, to order the inhabitants to live in peace with the Tibet, Kirghiz ("Kyrkyz"), Chinese ("Tapkach," or "renowned"), and Tatar peoples ("Tatar"). Another monument, unhappily broken in three pieces, stands to the south of the former; it dates from 733. A third monument of importance was found by Yadrintseff on the Onghin River, and it is concluded that it was erected in 692, in honour of Moghilian-khan. A monument on the Ikheaset seems to be of a later date than the two just mentioned. Twenty more monuments were erected in honour of different relatives of the Turkish Khan, Kyul teghin, who resided at Kara-balgasun. They have been found in the Minusinsk region, by Stralenberg, in the early part of the last century, and have been described since by several explorers, including Castrén. The reading of these inscriptions offers many difficulties, and Prof. Tomsen and Dr. Radloff are not quite agreed together as to the proper way of reading; so that more materials are wanted, and the Irkutsk Geographical Society is now busily at work to collect them.

Dr. Radloff, who thoroughly knows the old and the new Turkish dialects, has edited the book in a thoroughly scientific spirit; and if his readings are doubtful in certain places, this chiefly depends upon the incomplete preservation of the inscriptions themselves. From the dictionary and grammar given by Dr. Radloff, it appears that the language is a true Turkish dialect, quite harmonic, and nearly akin to the old Uigur dialect. In certain respects it even seems to be older than this latter, and the shades of sounds can be better rendered in the alphabet of the inscriptions than in the old Uigur alphabet. The old Turks had two alphabets in use: a variety of the Syrian, which goes under the name of Uigur alphabet, and the Arabian. A third alphabet must be added now to these two, and to the four which are in use amongst the modern Turks. It is worth noticing that, according to the Chinese historians, Indian writing was in use in East Turkestan; while in West Turkestan some other alphabet, "khu-shu"—*i.e.* barbarian—was in use. It was written in vertical columns, and it may have been the alphabet of the Orkhon and Yenisei inscriptions.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

By the will of the late Mr. Henry L. Pierce, Harvard University and the Massachusetts Institute of Technology each receive 50,000 dollars.

THE following are among recent announcements:—Dr. F. B. Peck to be associate professor of geology and palæontology at Lafayette College; Mr. Richard Rathbun to be assistant in charge of the Smithsonian Institution, in succession to the late Mr. W. C. Winlock.

A NUMBER of professors of the University of Berlin have addressed the Senate in order to obtain its approval for a movement in the nature of University extension, and it appears that the same course has been adopted in Jena and Leipzig. The Berlin correspondent of the *Times* states that the movement has met with an unexpectedly strong and widespread opposition. Many members of the classes which have themselves enjoyed University education object to the proposed extension, on the ground that the persons who are likely to take advantage of it will only receive from their attendance at the proposed lectures a most superficial kind of instruction, both in point of quality and of quantity.

A SKETCH of recent progress of technical education in England forms part of the ninth annual report of the National Association for the Promotion of Technical and Secondary Education. From this we learn that, in spite of the efforts made from time to time to secure for general county purposes certain portions of the funds belonging to education, the total sum annually set aside and utilised for educational purposes increases year by year. Of the forty-nine County Councils in England, forty are now giving all, and nine are giving part of their grants to educational purposes; while of the sixty-one county boroughs, fifty-five are devoting all, and five are devoting part of the fund in a like manner. The county borough of Preston is the only instance of an authority devoting all its grant to the relief of the rates. In considering the total amount of money devoted one way and another, it appears that of the 742,000*l.* annually available in England alone, no less a sum than 662,000*l.* is being spent on education. This is an advance of 62,000*l.* upon last year's figures, and is chiefly due to the rapid development of the work of the Technical Education Board of the London County Council. There thus remains a sum of 80,000*l.* still unappropriated to the purposes for which the fund was originally intended. Of this sum, however, London is responsible for 51,000*l.*, an amount which, there is every reason to believe, will shortly be required for the organisation of technical and secondary education in the metropolis.

THE number of technical schools which have been transferred to local authorities for municipal management and control has increased by four during the year covered by the above report, thus bringing up the total to 44. The four schools referred to are at Bradford-on-Avon, Gloucester, Leicester, and Lichfield. In the county borough of Huddersfield this matter is under consideration. Attention may also be directed to the operations of those local authorities in England which, upon their own initiative, have built, or are building, or are about to build, in the aggregate 115 technical schools, 101 of which involve an expenditure of 1,317,000*l.* This sum is derived from (1) the accumulation of funds under the Local Taxation Act, (2) loans raised by local authorities, (3) local subscriptions; the greater

proportion, however, is undoubtedly raised by loan. At the same time it is pointed out in the report that in two or three localities the entire fund was raised by donations and subscriptions, and in one instance, that of St. Helens, a site and 20,000*l.* was presented by Colonel Gamble, C.B., to the corporation for the establishment of a technical school and free library. Of the large number of technical schools mentioned above, 57 are already at work, 32 new schools having been opened since last year's report. There remain, therefore, 58 schools which, according to the latest information, are still incomplete. Dairy institutes or agricultural schools or colleges have been established by nine English County Councils. In addition to these, the establishment of a central agricultural school is under consideration in Cornwall, and the County Councils of the East, North, and West Ridings of Yorkshire are taking joint action with a view to forming a rural agricultural centre.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 19, 1896.—"Preliminary Report on the Results obtained with the Prismatic Camera during the Eclipse of 1896." By J. Norman Lockyer, C.B., F.R.S.

The author first states the circumstances under which Sir George Baden-Powell, K.C.M.G., M.P., with great public spirit, conveyed an eclipse party to Novaya Zemlya in his yacht *Otaria*, to which party was attached Mr. Shackleton, one of the computers employed by the Solar Physics Committee.

The prismatic camera employed, loaned from the Solar Physics Observatory, was carefully adjusted before leaving England, and a programme of exposures was drawn up based upon the experience of 1893. As the station occupied lay at some distance from the central line, this programme was reduced by Mr. Shackleton.

Two of the photographs obtained are reproduced for the information of other workers, as some time must elapse before the discussion of all the results can be completed. This discussion and Mr. Shackleton's report on the local arrangements and details of work, are promised in a subsequent communication.

The lines photographed in the "flash" at the commencement of totality—happily caught by Mr. Shackleton—the wave-lengths of which lines have been measured by Dr. W. J. S. Lockyer, show interesting variations from those photographed by Mr. Fowler in the cusp during the eclipse of 1893.

With the exception of the lines visible in the spectra of hydrogen and helium, and the longest lines of many of the metallic elements, considerable differences of intensity from the lines of Fraunhofer are noticeable.

The coronal rings have been again photographed, and the results of 1893 have been confirmed.

EDINBURGH.

Royal Society, January 4.—Prof. Chrystal in the chair.—Mr. T. S. Muir read the report of the intermediate station on Ben Nevis. He was stationed there from September 1 to September 23, and during that time he took 186 observations, or eight readings per day. Out of twenty-two times that the barometer at the intermediate station (reduced to 32° and sea-level) read higher than that at Fort William, fourteen occurred close together during the first four days of the month, and were followed by a period of fine weather. On the average the intermediate barometer read one-hundredth of an inch lower than the Fort William barometer, and the weather of the month generally was bad. The mean day-difference of temperature between the intermediate, summit, and Fort William stations was as nearly as possible half of that between the summit and the base. But it is probable that during the night the intermediate temperature comes closer to that of the summit, and that the average for the twenty-four hours is closer to that of the summit than Fort William. When the station was enveloped in fog, or between two fog-systems, or close to the fog, the temperature approximated to that of the summit, and when there was no fog visible, or, if it were, at a great height, it approximated to that of the base. Also, when the sky was overcast, or nearly so, the middle temperature was closer to that of the summit; when the sky was clear, to that at Fort William. During the period, the rainfall at the summit was 6½ inches, at the intermediate station 6 inches, and at Fort William 4¾ inches.

Dr. Munro read a paper on intermediary links between man and the lower animals. He maintained that by the attainment of the erect posture and the consequent conversion of the limbs into hands and feet man became *Homo sapiens*, and inaugurated a new phase of existence, by means of which the manipulative organs became correlated with the progressive development of the brain. In the evolutionary career of man two stages were therefore to be recognised. First, that during which his physical transformation had been effected, so as to adapt him to bipedal locomotion; second, that during which his mental organisation had become a new governing force in the universe. The one, being readily effected according to the laws of morphological adaptation, had a short duration. The other, an extremely slow process, consisted of small increments to his knowledge, acquired by repeated experiences, and reasoning from causes to effects, and from means to ends. The one was merely an adjustment of physical contrivances to physical ends, comparable to that by which the bird, the bat, or the whale had converted its limbs to their special purposes. The other had to be relegated to the mystic laboratory where thought was converted into its material equivalent in the form of increased brain substance. The transition from the semi-erect to the erect posture could not, in point of duration, be at all paralleled with the ages during which this erect being had lived on the globe. It was also probable that this transformation took place in a limited area; so that the chances of finding the intermediary links of this stage were very small. On the other hand, the probability of finding erect beings with skulls in all grades of development, from a slightly changed Simian type up to that of civilised man, was enormously greater. He regarded the erect posture as the most conspicuous line of demarcation between man and the lower animals. From this standpoint, the Java skeleton would come under the category of human; but if this line of distinction was to be dependent in any degree on mental phenomena, Dr. Dubois was perfectly justified in regarding it as a transitional form, because it was a long time after the attainment of the erect posture, before his religious, moral, and intellectual faculties became human characteristics. Dr. Munro believed that many fossil remains of man were intermediary links which marked different stages in the history of mankind, and the further back such investigations carried them, the more Simian-like did the brain-case become. If the geological horizon of the Java man was correctly defined as the borderland between the Pliocene and Quaternary periods, they could form some idea how far back they had to travel to reach the common stock from which men and anthropoid animals had sprung. The lower races of to-day were also survivals of intermediary links which had been thrown into the side eddies of the great stream of evolution.

PARIS.

Academy of Sciences, January 4.—M. A. Cornu in the chair.—Researches on the physiology of muscular action, by MM. A. Chauveau and J. Tissot. When the weight sustained by a muscle and the amount by which it shortens increase together, it is shown experimentally that the respiratory exchanges which represent the energy spent, that is, the oxygen absorbed and the carbon dioxide exhaled, increase as the product of the shortening by the weight.—On a generating and distributing apparatus for acetylene, by M. H. L. Lechappe.—Observations on the new Perrine comet (December 8, 1896) made at the Observatory of Algiers, by MM. Rambaud and F. Sy.—On the consumption of water in locomotives, by M. E. Vicaire. On the basis of some experiments carried out on the Orleans system of railways, a general expression is deduced for the consumption of water on any given section.—Variation of the accidental double refraction of quartz with the direction of the compression, by M. R. Dongier. It is found that the same pressure, applied in two independent directions normal to the ternary axis, affects the wave-surface differently. The experiments will be continued with a view of determining the exact relation between the direction of pressure and the double refraction produced.—The action exercised upon solutions of the haloid salts of the alkalis, by the bases that they contain, by M. A. Ditte. An experimental study of the decrease of solubility of KBr by the addition of a solution of caustic potash, and of NaBr, by caustic soda.—Action of ammonia upon tellurium chloride. Tellurium nitride, by M. René Metzner. At 200°—250° C., $TeCl_4$ is slowly but completely reduced to metallic tellurium, ammonium chloride and nitrogen being formed. At

0° C. the action is quite different, the compound $TeCl_4 : 3\,NH_3$ being produced. Under certain conditions, somewhat difficult to realise, tellurium nitride, TeN, arises by the spontaneous decomposition of this ammoniacal chloride. The nitride is unstable, detonating violently when struck or heated, but is not attacked by water or by dilute acetic acid. —On the absorption of sulphuretted hydrogen by liquid sulphur, by M. A. H. Pélabon. Liquid sulphur at 440° C. absorbs hydrogen sulphide, which it gives out on solidifying. This can scarcely be a true case of a solution of a gas in a liquid, as it is found that the amount absorbed increases with the temperature, and is only given out on solidifying, no gas being given out by the solution in liquid sulphur even into a vacuum.—On the production of vanilline with the aid of vanilloylcarboxylic acid, by M. Ch. Gassmann.—On the transformation of eugenol into isoeugenol, by M. Ch. Gassmann.—On the principal varieties of wheat consumed in France, by M. Balland. Analyses of wheat from various sources.—Influence of the nervous system on the effects obtained by the injection of serum from vaccinated animals, by MM. Charrin and Nittis. As a general result it was found that lesions of the nervous system, which, as a rule, favour infection, also interfere with the protective power of a serum.—Influence of the different psychic processes upon the blood pressure in man, by MM. A. Binet and N. Vaschide. In all the experiments the blood pressure was increased. This effect was produced by pain, a strong mental effort, conversation, and a fatiguing muscular effort.—The Malpighian tubes of the Orthoptera, by M. L. Bordas.—On the *Spirorbis*; asymmetry of these annelids and in the classification of this and allied species, by MM. Maurice Caullery and Félix Mesnil.—Remarks on the above note, by M. Edmond Perrier.—On the geological history of the Vosges, by M. A. de Lapparent.—On the period of formation of the phosphatic sands at the surface of the brown chalk, by M. Stanislas Meunier. Some remarks on a note by M. de Mercey.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 14.

MATHEMATICAL SOCIETY, at 8.—Supplementary Note on Matrices: J. Brill.—The Partition of a Number into Primes: Prof. Sylvester, F.R.S.—Some Properties of Bessel's Functions: Dr. Hobson, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Inaugural Address of the President, Sir Henry Mance.

SOUTH LONDON ENTOMOLOGICAL AND NATURAL HISTORY SOCIETY.—Some Marine Mimics: E. Step.

FRIDAY, JANUARY 15.

EPIDEMIOLOGICAL SOCIETY, at 8.—Age Incidence in Relation with Cycles of Disease Prevalence: Dr. Hamer.

INSTITUTION OF CIVIL ENGINEERS, at 8.—On "Monier" Girders and Arches: Walter Beer.

SUNDAY, JANUARY 17.

SUNDAY LECTURE SOCIETY, at 4.—The Mountains of Great Britain: Prof. Norman Collie, F.R.S.

MONDAY, JANUARY 18.

SOCIETY OF ARTS, at 8.—Material and Design in Pottery: William Burton.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The Character of the London Water Supply: W. J. Dibdin.

VICTORIA INSTITUTE, at 4.30.—On the Assouan Embankment: Prof. Hull, F.R.S.

TUESDAY, JANUARY 19.

ROYAL INSTITUTION, at 3.—Animal Electricity: Prof. A. D. Waller, F.R.S.

ROYAL GEOGRAPHICAL SOCIETY, at 4.30.—Sand Dunes: Vaughan Cornish.

ZOOLOGICAL SOCIETY, at 8.30.—Revision of the West Indian Micro-lepidoptera, with Description of New Species: Lord Walsingham, F.R.S.—On some Points in the Anatomy of the Manatee lately living in the Society's Gardens: F. E. Beddard, F.R.S.—On the Classification of the Primates from the Ophthalmoscopic Appearance of the Fundus oculi: Dr. G. Lindsay Johnson.

ROYAL STATISTICAL SOCIETY, at 5.30.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: Superheated Steam Engine Trials: Prof. W. Ripper.—Papers to be read, time permitting: The Diversion of the Periyar: Colonel J. Pennycuick, C.S.I., R.E.—The Periyar Tunnel: M. P. Roscoe Allen.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—The History of the Half-tone Dot: W. Gamble.

GRESHAM COLLEGE, at 6.—Minute Organisms as Causes of Disease: Dr. Symes Thompson.

WEDNESDAY, JANUARY 20.

SOCIETY OF ARTS, at 8.—The Roller Boat of M. Bazin: Emile Gautier.

GEOLOGICAL SOCIETY, at 8.—On Glacial Phenomena of Palæozoic Age in the Varanger Fjord; The Raised Beaches and Glacial Deposits of the Varanger Fjord: Aubrey Strahan.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Report of the Council; Election of Officers and Council.—Address on Shade Temperature: E. Mawley, President.

ROYAL MICROSCOPICAL SOCIETY, at 8.—President's Address.

ENTOMOLOGICAL SOCIETY, at 8.—Annual Meeting.

GRESHAM COLLEGE, at 6.—Bacteria in Air and Water: Dr. Symes Thompson.

THURSDAY, JANUARY 21.

ROYAL SOCIETY, at 4.30.—The following Papers will *probably* be read:—On Cheirostrobus, a New Type of Fossil Cone from the Calciferous Sandstone: Dr. D. H. Scott, F.R.S.—(1) Experiments in Examination of the Peripheral Distribution of the Fibres of the Posterior Roots of some Spinal Nerves, Part II.; (2) Cataleptoid Reflexes in the Monkey; (3) On Reciprocal Innervation of Antagonistic Muscles (third note): Prof. Sherrington, F.R.S.

ROYAL INSTITUTION, at 3.—Some Secrets of Crystals: Prof. H. A. Miers, F.R.S.

LINNEAN SOCIETY, at 8.—On the Origin of the Corpus callosum; a Comparative Study of the Hippocampal Region of the Cerebrum of Marsupialia and certain Cheiropteræ: Dr. G. Elliott Smith.—On the Minute Structure of the Nervous System of the Mollusca: Dr. J. Gilchrist.

CHEMICAL SOCIETY, at 8.—Studies of the Properties of Highly Purified Substances. I. The Influence of Moisture on the Production of Ozone from Oxygen and on the Stability of Ozone. II. The Behaviour of Chlorine, Bromine, and Iodine with Mercury. III. The Behaviour of Chlorine under the Influence of the Silent Discharge of Electricity and in Sunlight: W. A. Shenstone.—Action of Diastase on Starch, Part III.: A. R. Ling and J. L. Baker.—The Solution Density and Cupric-reducing Power of Dextrose, Levulose, and Moist Sugar: Horace T. Brown, F.R.S.; Dr. G. Harris Morris; J. H. Millar.—Derivatives of Maclurin, Part II.: A. G. Perkin.

GRESHAM COLLEGE, at 6.—Milk, Meat, and Oysters as Carriers of Disease: Dr. Symes Thompson.

FRIDAY, JANUARY 22.

ROYAL INSTITUTION, at 9.—Properties of Liquid Oxygen: Prof. Dewar, F.R.S.

PHYSICAL SOCIETY, at 5.—An Exhibition of some Simple Apparatus by W. B. Croft.—On the Passage of Electricity through Gases: E. C. Baly.

GRESHAM COLLEGE, at 6.—Diphtheria: Dr. Symes Thompson.

THURSDAY, JANUARY 21, 1897.

OUT-DOOR STUDIES OF NATURE.

The Round of the Year, a Series of Short Nature Studies. By Prof. L. C. Miall, F.R.S. Pp. 295. (London: Macmillan and Co., Ltd., 1896.)

Life in Ponds and Streams. By W. Furneaux, F.R.G.S. Pp. vi + 406. (London: Longmans, Green, and Co., 1896.)

BOTH these volumes, while aiming at scientific accuracy, are intended for the general reader; and, on this account, they have a considerable value.

Prof. Miall's "Round the Year" is quite an unique book. The study of a lofty model is sure to inspire us, intellectually or morally; and a close study of Gilbert White is manifest in most of his extremely interesting pages. They constitute a group of sketches growing out of the events of the year 1895; a year, in some respects, of unusual interest to the naturalist.

It is somewhat rare in these days to find a book, written almost entirely on biological subjects, so happily free from the laboratory, and its technicalities and methods. We see Prof. Miall as an observer, and by the very manner of his observations showing the amateur and the young mind interested in nature how to observe. This is aided rather than hindered by the very wide and even desultory character of the subjects which in this volume claim his attention. In the very first pages he introduces his reader to a fascinating account of some *Simulium larvæ*, found in "a clear and rapid stream which flows down from the moors of the Wharfe." This affords precisely the description of facts and circumstances likely to arrest and fix the attention of the hesitating as to whether or not he will make nature the subject of his special study.

These and the following few pages on insects and plants in midwinter are precisely what we need at this time. The amateur is diverted from the study of nature by the enormous mass of "facts" accumulated in the laboratory, having no doubt inestimable value, but compiled by men who, to those outside the specialist circle, appear little concerned with nature in the sense in which it was so beautiful to, and made so interesting by Gilbert White. The danger is lest we should, in modern days, cause the majority to conclude that the world must be divided into scientific and non-scientific; which in effect means into specialists and general readers. The intermediate order of mind, deeply observant of, and interested in, nature, is rarely considered. But it is to this class of mind that Prof. Miall appeals; and he does it with all the accuracy of a sound man of science, and all the simplicity of a natural lover of the objects he contemplates.

Some of the notes, such as "Snow-flakes," presenting as they do the latest results, will perhaps not be readily assimilated by the reader for whom these notes are really written; but ever and again we come upon the keen clear observations of a man as independent of text-books as he is of tutors: an observer whose observations will lead others to do likewise. His notes on "Phi and Theta"[1] are especially of this order, and while they incorporate the latest scientific investigation easily lead the non-scientific observer to see what possibilities of pleasant observation lie around him.

A very interesting paper is that on "Animals with and without Combs." "The Oil-Beetle (*Meloe*)" is another cluster of notes which we heartily commend to the general reader. But there is something quite fresh in "The Corn-rigs of Beamsley Fell," and in this we see the author's knowledge and love of Yorkshire.

Some very interesting matter not commonly thrown together is given on "The Cuckoo," in which the problem of the cuckoo's action in regard to her egg is very cleverly presented.

The "Botany of a Railway Station" is well worthy of the ordinary reader's study; and the notes on "Hay-time" and on "Moorland Plants" will quicken the interest of many in what is still known as "natural history."

The note on the "Reversed Spiral" is of great value; quite by incident, it will show the general reader how some of the most remarkable adaptations—"contrivances"—in nature are in reality not such. "The reversed spiral (with all its wonderful perfections of 'adaptation') is not a contrivance at all; it is a mechanical necessity when a band whose ends are not free to revolve is thrown into coils."

"The Structure of a Feather" and "The Fall of the Leaf" are not new, but clear and so presented that the readers for whom the book is written, and to whom it will be fresh, will find in it an uncommon interest. In short, this book worthily represents its author. A student of the deeper things of nature, he has pleasure, manifest in every page, in presenting to others the results of general observation, which may awake in them the keenest delight.

Mr. Furneaux's book on "Life in Ponds and Streams" is remarkably well presented to the reader. The publishers' work has been admirably done; and to those who have read "The Out-door World," there will be little doubt that in this book we have a thoroughly practical treatise. In fact this is not a book to "read"; it is a book to be taken as a guide to the practical study of the ponds and streams.

It was ponds and streams that led to the whole science of microscopic research; and whilst this book deals with the larger inhabitants of the pool and the brook, it is of exactly the order that is needed to awake an interest in living things far beyond the limits it has wisely set itself. The "introduction" is a useful epitome of the animal kingdom so far as it will be needed by the collector; and the practical hints and instructions on collecting are such as could only have been given by an experienced leader; and we may say that the careful reader of the chapters on "Collecting in Ponds and Streams" and "Collecting Minute Forms of Life," will not suffer much from embarking on his task with supreme trust in his guide. We think that the instructions given to the possessor of a moderately good modern microscope—and the English market is now crowded with the very best models at the very lowest price—as to how to make a "*spot-lens*" are, however, quite superfluous, for the simplest substage condenser ought to be supplied with

[1] A dog and cat.

the means of getting all the results the "spot-lens" can give, and we very heartily hope that even low powers are now rarely used without a suitable condenser. This, however, is a detail, and leaves the instructions to the tyro on this head with very little to be desired.

"The Pond Hunter's Museum" and "Aquaria and their Management," are both chapters of great value, and they are written by one who has realised the pleasures and the difficulties they involve. And after this we enter upon the supreme purpose of the book—the life which the pond and the stream reveals. For the purpose which the writer had in view it is not easy to conceive of a more practical and thorough treatment of his subject, and withal one which would enable the least initiated to follow more intelligently, and at the pond-side, what this book incites him to study.

It is not with the lower and minuter forms of life that the author chiefly concerns himself. These are lightly touched, affording ample room for future study. But worms, leeches, molluscs, crustaceans, spiders, aquatic insects, fishes and amphibians, form the main subjects of study.

In this region of study, as in all others, wonderful advances have been made. The pond-hunter of twenty-five years ago would have found a treasure indeed in a book like this. Its thoroughness and its admirable illustrations taken together give it a great value to the youth who happily determines to make the life of the pond or the stream his hobby; and if it never goes beyond that point, this volume will have served an admirable purpose. But the book is so well written, and is capable of inciting so much interest, that we believe it will accomplish a deeper and more lasting purpose

W. H. D.

THE LUNAR THEORY.

An Introductory Treatise on the Lunar Theory. By Prof. E. W. Brown, M.A. Pp. xvi + 292. (London: Cambridge University Press, 1896.)

THE design of this valuable text-book on the lunar theory is similar to that of Tisserand's "Mécanique Céleste," the object in both cases being to lay before the reader the methods by which various practical problems of gravitational astronomy have been attacked. In each case the recent pure mathematical investigations of Poincaré, Lindstedt, Gyldén, &c., though not passed by without notice, evidently form but a small part of the author's plan. Of the two writers, Prof. Brown is by far the least ambitious; and his work does not extend, like Tisserand's, to planetary theory, figure of the earth, precession, and other gravitational problems that form so large a part of the most recent "Mécanique Céleste." We venture to think, however, that Prof. Brown has dealt with his more limited subject in a manner that is far clearer, more thorough, and more useful to the student.

Prof. Brown has not attempted to follow any theory through all the approximations that are necessary for obtaining an orbit that shall represent the moon's path within the limits of observation, neither are the huge masses of figures necessary for such a task reproduced in the treatise. There is no mathematical point that cannot be sufficiently illustrated by the third approximation, or terms depending on the square of the disturbing force. The author has therefore limited himself generally to the first approximation, or intermediate orbit; to the second approximation, depending on the first power of the disturbing force; and to the third approximation, depending on the square of the disturbing force. In connection with the first approximation the author discusses the choice of an intermediate orbit, and in the case where this orbit is an ellipse he shows why it was necessary to modify it so as to represent the motion of the node and apse. Various elliptic formulæ are also given, including the application of Bessel's Functions. A theorem of Hansen's is also given, that is subsequently employed.

For a second approximation the author shows that in practice the earth's mass may be neglected in comparison with the sun's, and that subject to a simple modification in the final result the moon's mass may be neglected altogether, or rather assigned to the earth. A numerical estimate—which we believe is original—is given of the magnitude of the errors involved in these assumptions. In this connection we should like to enter a protest against the calculation of terms depending on the square of the sun's parallax when the moon's mass is neglected. The modification, above referred to, does not correct these terms; they cannot in any way be made to represent an actual phenomenon: they are, as it happens, small enough to be negligible—were this not so, the method would have to be altered in order to compute them.

The disturbing function is also developed in different ways suitable for different theories. The differential equations of disturbed motion are also obtained. In the integration, various points are carefully discussed. The most important of these is the way in which terms proportional to the time might occur, the way in which such terms are got rid of, and the interpretation of this artifice—due to Clairaut—as representing a motion of the node and apse. Another point is the meaning of the constants of integration; when, for instance, the motion is no longer elliptic, the notion of the eccentricity becomes somewhat vague. In order to render two theories comparable, the arbitrary constants of one must be expressed in terms of those of the other; and hence it is desirable in every theory to have a clear conception of the meaning—if possible the physical meaning—of the constants. Again, at every fresh approximation fresh constants arise as part of the "complementary function." What to do with these constants requires careful consideration; sometimes one has to be left arbitrary for a time, in order that it may be used later to remove terms depending on the time; more often—and the preceding case is really only a special case of this—they may be used to suitably modify or to define more exactly the constants that have previously arisen. These points are of fundamental importance, and are rightly dealt with by Prof. Brown at considerable length.

The difficulties of a third approximation chiefly consist in the necessity for computing the disturbing forces with the disturbed coordinates already obtained. An example is given from De Pontécoulant's method.

Prof. Brown also discusses the general form of the final result. Every argument must be the sum or difference of integral multiples of four angles, and the characteristic

of each coefficient—that is to say, its order in the eccentricities, inclination, and solar parallax—can be written down by inspection, and is not modified by any integration or other process that occurs in the computations. The order, however, in the ratio of the mean motions does not follow any simple law. This is due to the fact that certain terms rise in importance on integration. The class of terms that behave thus is carefully pointed out in the book, and the fact that their consequent increase in importance is transmitted to the terms in *queue* with them, thereby doubling the number of approximations necessary, is noticed. As far as we know, the whole question has never been thoroughly gone into, so as to form rules whereby the order in the mean motions of every term may be estimated. It would form a fitting subject for a thorough investigation. For instance, with Delaunay's notation, the term with argument $2D$ is of order m^2, the term with argument $2D - l$ has been lowered by one order in m to me. The term in $4D + l$ may be considered as made up of $2D + 2D + l$, $2D + (2D - l) + 2l$, or $(2D - l) + (2D - l) + 3l$, and its order will be m^4e, m^3e^3, m^2e^5 in the three cases. Similarly the order of the term in $4D - l$ is m^3e and m^2e^3. These are simple cases illustrating the fact that lower powers of m often occur than the power by which the characteristic part of the coefficient is multiplied.

The treatise deals with four theories in some detail—De Pontécoulant's, Hansen's, Delaunay's and Hill's. De Pontécoulant's is an easy one to understand, and the author has attached to it his discussions of the constants and other points that are in reality common to all theories in variously modified forms.

Hansen's theory is an extremely difficult one, and Tisserand has entirely failed to give an intelligible account of it. Prof. Brown, too, leaves something to be desired; but we at least owe to him a remarkable simplification in an introductory lemma (recently published in the *Monthly Notices*). The proof given by Prof. Brown is so simple, that its merit is only apparent to those who have read Hansen's investigation of the same point. Hansen's theory is of a curious design: the inequalities are thrown upon the time or the mean longitude. Dr. Hill considers that the method was an outcome of an extension to all terms of a method used by Laplace for terms of long period.

Delaunay's theory is a gigantic task representing twenty years' labour. His method is the variation of arbitrary constants, using canonical equations. Prof. Brown has considerably simplified the introductory analysis on which the theory rests, and has recently published a further simplification in the *Proceedings* of the London Mathematical Society.

Dr. Hill's theory is the most recent, and the simplest in form. It is, however, as yet far from complete. It was, as is well known, originated by some papers of Dr. Hill's in the first volume of the *American Journal* and the eighth volume of the *Acta Mathematica*. In these papers Dr. Hill obtains the variation curve (that does duty as the intermediate orbit) and the motion of the perigee. The further development has been left almost entirely to Prof. Brown, who has published a series of papers in the *American Journal*. Among these is a paper of great analytical interest containing some theorems that include two famous theorems of Adams' as a special case. It is much to be wished that Dr. Hill's theory should be completed.

The book concludes with a short sketch of several other theories, and the methods used in computing inequalities other than those due to the sun.

OUR BOOK SHELF.

Chemistry for Engineers and Manufacturers. A Practical Text-book. By B. Blount and A. G. Bloxam. Vol. ii. *Chemistry of Manufacturing Processes.* Pp. 484. (London: C. Griffin and Co., Ltd., 1896.)

IT is stated in the preface that the sole object of this work is to give the reader a general view of the principles which underlie the several manufactures described. The ground covered is very wide, so that in order to keep the book within reasonable limits a very condensed style has been adopted. The opening chapters deal with the manufacture of sulphuric acid and alkali, and the destructive distillation of coal, wood, and bone, the account of coal-gas manufacture being especially well done, although the short account of methods of gas-testing is sketchy and inadequate, and might have been omitted with advantage. The subjects of artificial manures, petroleum, cement, glass and porcelain, sugar and starch, brewing and distilling, oils, resins and varnishes, are next dealt with. The soap and candle industry is dismissed in nine pages, no account being given of the chemistry of the "cold process" of soap-making, in which the excess of alkali is eliminated by the subsequent addition of ammonium salts, although most of the highest grades of toilet soaps are now prepared by this process. The chapter on dye-stuffs, which follows, contains a good synopsis of the chemistry of this subject. It is, however, too brief to be of much service to the dye-works chemist, and is certainly beyond the apprehension of the average engineer.

The authors, indeed, are rather optimistic in their estimate of the chemical knowledge possessed by engineers, as chemical formulæ and equations are freely used throughout the book. Of the remaining chapters, those dealing with the preparation of pigments, leather, and explosives are the most important. In view of the growing importance of cyanide compounds in gold extraction, it is to be hoped that a little more space will be found for this subject in the next edition, no mention being made of the recent advances in the industrial applications of the well-known synthesis from alkalis, carbon, and gaseous nitrogen. The short bibliography at the end of the book will prove useful in following up the details of any particular subject.

The Struggle of the Nations. By G. Maspero. Edited by A. H. Sayce, and translated by M. L. McClure. (Society for Promoting Christian Knowledge, 1896.)

SOME time ago (see NATURE, No. 1310) we called the attention of our readers to the issue of a much enlarged and illustrated edition of M. Maspero's work "Histoire Ancienne des Peuples de l'Orient Classique" in a notice of the first volume, which appeared in England under the title of "The Dawn of Civilization," and we welcomed it as a book much to be desired. The second volume now before us is the next instalment of the edition, and we welcome it no less gladly; it is to be hoped that the intervals between the issue of the volumes will become shorter and shorter, and that the whole work may be in our hands in a few years. The period covered by the first volume extended from the time when we first have written records in Egypt and Western Asia (including Babylonia) to the end of the reign of the kings of the twelfth dynasty in Egypt, say about B.C. 2500; in this volume we are led from the time of Khammurabi and his immediate predecessors to the end of the twenty-first

dynasty, about B.C. 1100. The nations discussed in the earlier volume were comparatively few, but when we turn to the later one we see that it treats of the history of all the peoples who lived in the countries which lie between Elam on the east, Cyprus on the west, Armenia on the north, and Berber on the south. How they arose, gained power, made war and invaded each other's territories, attained the zenith of their glory, were conquered, and were finally destroyed or merged in the ascending might of their neighbours, M. Maspero has undertaken to tell; and we think that he has carried out his task very fairly well. The overwhelming mass of notes and references to authorities testify to immense energy, and to a desire to put the reader in possession of a large number of facts. In the course of his work he has touched upon a variety of "burning questions," such as the Hyksos, the Hittites, the Exodus, &c., and we are tolerably certain that he will not please every one who reads his book; on many points we ourselves should disagree with him. To discuss these differences would require more space than we are allotted, and it is only fair to say that the general plan of the work is excellent, and that the author has spared no pains to make it a useful guide to the knowledge of Oriental history. On certain subjects his information is not obtained at first hand, but when we consider that he has to deal with Egyptians, Babylonians, Assyrians, Cosseans, Kassites, Elamites, Hittites, Arameans, Syrians, Hebrews, and others, this cannot be wondered at; and that he should be led away, at times, by his authorities is quite excusable. His chapters on Egyptian history are, as might be expected, worthy of his reputation.

The Camera and the Pen. By T. C. Hepworth, F.C.S. Pp. 64. (Bradford: Percy Lund, Humphries, and Co. Ltd., 1896.)

RELIEF blocks produced without the aid of the engraver are now extremely common—rarely do blocks of any other kind appear in NATURE—yet it is astonishing how very hazy are the ideas which the majority of people have as to the way they are made. In this slender volume will be found a sketch of the methods employed to produce line blocks and half-tone blocks, and we trust it will be widely read; for a knowledge of the possibilities of process work would often save the production of a bad block. The simplest form of process block is that made from line drawings, or pen-and-ink sketches. To obtain the best effect, the drawing should be made on Bristol board, or similar white surface, in very black ink. Liquid india ink is commonly used, but Stephens' ebony stain is sometimes preferred. This is photographed by the process worker, and, by a simple arrangement, a reversed negative is obtained. A sheet of zinc, covered with a substance which becomes insoluble after exposure to light, is placed in contact with this negative, and afterwards the unaltered parts are washed or rubbed off. The zinc plate thus marked is then etched, and eventually mounted on wood ready for the printing machine. It will be evident, then, that drawings to be used for the production of blocks in this way should be very distinct, and no lines or marks should be upon them but what are required to appear in the figure. The half-tone process is used for the reproduction of pictures other than line drawings. For illustrations of natural things and phenomena, where accuracy is all-important, reproduction by photographic process may be said to be essential. The only conditions for satisfactory results are clear pictures, which may be either negatives or positives.

Many hints of interest to photographers, as well as very instructive information on the processes of manufacturing blocks for illustration purposes, will be found in Mr. Hepworth's book. The only complaint which is likely to be raised about the contents is that they are deficient in details.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Bog Slides and Debacles.

THESE slides have been brought very prominently forward on account of the recent debacle near Gneevegullia, Co. Kerry. They are a subject that ought to be known and understood, as numerous observers and writers have brought the subject before the public since Gerrard Boate wrote on bogs in A.D. 1652, up to the present time.

If, however, we are to judge from what has been lately written, the public seem to be supposed to consider such a slide as that in Kerry as something quite out of the common, which no one can understand. But, on the contrary, bog slides and debacles are one of the numerous Irish disturbances, that lie dormant for a time and burst forth suddenly when least expected—take Gneevegullia Bog as an illustration. It is situated on the watershed of the Brown Flesk, a tributary of the Maine, the Blackwater and the Flesk, into all which rivers at times it sent squirts, but especially in late years, into the Quagmire River, a tributary of the Flesk. Into the latter river it sent a considerable squirt three or four years ago; now it breaks forth into the Flesk instead of the Brown Flesk; where it was always expected to go.

Small slides and debacles of both bogs and drifts, in the Irish hill groups, are not uncommon, and any frequenter of the hills must at some time or another have seen one. They give the observer a very nasty sensation. Suddenly he sees a curious shiver in a bog flat; at first he considers it to be only the shimmery air over the bog, so usual in hot weather, but presently he sees a "creeping where no life is seen," with a black steam or sheet issuing from it. Ten to one he immediately jumps up to make sure that his seat has not also taken to walking. Most bog slides are hard to see, as they usually take place during the night; there are, however, exceptions to this general rule, as the famous slide in the Ballykillim Bog, near Clara (1825), took place while the turf-cutters were at their dinner, and the slide on March 28, 1745, near Dunmore, Co. Galway, also took place in the day-time, and the turf-cutters had to run for their lives.

In the annals of the Four Masters there are records that must refer to either water-spouts or bog debacles, but they are too vague to quote. Gerrard Boate, in 1652, tells us how to drain a "shaking bog," but he does not record any movements. The first I know of is the communication to the Royal Society in 1697, by W. Molyneux, of the Bog of Kapanihan, Co. Limerick, near Charleville. As this began at 7 p.m. on June 7, 1697, the first movement of this bog could be described; afterwards he gives the final results, and the causes that made the movements. The newspaper reports at the time talk of the accompanying great noise; Molyneux, however, says there was none. The Bishop of Clogher also gives a good scientific account of a bog movement near Clogher on March 10, 1712; but the majority of the other records are by men who have gone in for sensation. This has been the case in the recent reports. No one knows when the movement began in the Gneevegullia Bog, but now we are told it was heralded in by noises and great shaking.

The printed records of big slides or debacles that I have read (as far as I can remember) are the following:—

1607. June 7. Kilpaniham, near Charleville, Co. Limerick.
1708. Castlegarde, Co. Limerick.
1712. March 10. Near Clogher. This bog had also moved, according to tradition, before 1640.
1745. March 28. Addergot, near Dunmore, Co. Galway.
1780. Monabogh, Dundrum, Co. Tipperary.
1819. Valley of the Owenmore, Erris, Co. Mayo.
1821. Slip in Joyce County, Co. Galway.
1824. December 22. Ballyroindallow Bog, near Coleraine.
1825 (?). Kilmalady Bog, near Clara, King's Co. Fasset Bog, 16 miles away, also moved, but did not burst forth.
1867. Glen Castle Hills, Belmullet, Erris, Co. Mayo.
1871 (?). In the Valley of the Suck, alongside one of the Roscommon tributaries.
1871 (?). Clonagill, near Birr, King's Co.

Other big slides will be found recorded by Lewis, but it would take time to go over all his County histories.

Every slide and debacle is due to the combined effects of great drought succeeded by heavy wet. In the majority of the bogs, of any extent, and even in some of very small dimensions, there are in parts "shaky bogs." Those portions in great drought dry and contract, thereby being traversed by fissures, and more or less broken away from their soles. When the rains descend and the floods come, the water first saturates and floats the lower portions and afterwards the upper portions. The latter process has a peculiar appearance. When a bog is saturated, on its highest part there is generally a Loughaun, *i.e.* a pool without any surface outlet. During a drought the bog about the Loughaun sinks, while it often becomes quite dry; but when the rains come, the bog swells just like a dry sponge put in water, and rises the Loughaun along with it. When a bog is saturated its lower portion is a sea of mud surrounded by a hard margin. If this margin in any place gives way there is a bursting forth ("debacle"), as in the recent case in Kerry, but sometimes the bog will over-swell, as in the case described by Molyneux, when the bog will begin "to walk" on its own account, and in its course lift up and carry away the barrier.

Different slides, such as that near Clara, that near Dunmore, and the recent one, were due to the turf-cutters, who weakened the barriers. Turf may be cut on two systems—"Brest banks," or banks opened round the margin of a bog or along a road; and banks that are more or less perpendicular to the margin of a bog or a bog road. The latter class of banks prevent slides, as they act as drains to the mass of the bog; while the Brest banks facilitate slides, as possibly may be exemplified this coming season, when the Brest banks are being cut.

Naturally it will be asked why all the bogs are not cut on the perpendicular system? The answer to which is, that it has been generally adopted in the mountain districts; but in the Low Land deep bogs this is nearly impracticable, as it would take years before you could run your bank into them, while all the time you would be at a dead loss. This, however, is a subject outside the present inquiry.

During my years of tramping the Irish hills, I have seen some interesting aspects of bog and drift slides; but it is unnecessary to recapitulate them here, as any one interested can fully read up the subject in previous publications.

It may, however, be allowable to point out that the different writers on the late Kerry debacle, apparently never saw the site of a previous debacle, or they would not make the foolish suggestions that have appeared in their writing.

I visited the Owenmore site about 1875, or about fifty years after its occurrence. This is the most disastrous slide on record, as it carried away a whole village and its inhabitants, also a picket of Highlanders, whose bodies were afterwards pinked up in Tullaghan Bay. When I saw it there was nothing very remarkable about the bog; it had a nice hollow in it, with a pollagh for snipe and duck; but if I had not been told to the contrary, I would have seen nothing very extraordinary about it. Of similarly other sites that I have visited, that in the Joyce country is now a heathy hollow, a good place for grouse; while that on the Glencastle Hill slope, when visited ten years after, could scarcely be detected, except that at the north end of the townland, adjoining the road and Broad Haven, there was a tumbling up in hummocks, partly drift, partly bog.

A new gulch, due to a debacle, is hard to cross, if not impassable, for a year or two; after which time the bog will have soaked, and the bog-mould slopes will begin to consolidate and grow vegetation; once they have a sod on them all appearances of the debacle rapidly disappear, so much so, that only one person out of a hundred, if you undertook to explain to him what had formed a gulch in a mountain slope, would believe you; the other ninety-nine would say "Hookey Walker!"

The bog, the site of the recent slide, is not more than 20 or 30 feet deep; this will contract at each side of the gulch so as to leave a hollow not more than from 10 to 15 feet deep, as has elsewhere been practically proved.

G. HENRY KINAHAN,
District Surveyor (Retired), H.M. Geol. Survey.

On the Goldbach-Euler Theorem concerning Primes.

I HAVE verified the new law for all the even numbers from 2 to 1000, but will not encumber the pages of NATURE with the details. The approximate formula hazarded for the number of resolutions of $2n$ into two primes, viz. $\frac{\mu^2}{n}$, where μ is the number of mid-primes, does not always come near to the true value. I have reasons for thinking that when n is sufficiently great, $\frac{\mu^2}{2n}$ may possibly be an inferior limit. The generating function

$$\left[\Sigma \frac{1}{1-x^p}\right]^2$$

given in a recent number of NATURE, p. 196, is subject to a singular correction when the partible number $2n$ is the double of a prime. In this case, since the development to be squared is

$$\mu + x^n + x^{2n} + \ldots + x^p + x^{2p} + \ldots +, \&c.,$$

the coefficient of x^{2n} will contain 2μ, arising from the combination of o with $2n$, which is foreign to the question, and accordingly the result given by the generating function would be too great by 2μ.

This may be provided against by always rejecting the centre of the mid-range from the number of mid-primes. The formula will then in all cases give twice the number of ways of breaking up $2n$ into two unequal primes. Another method would be to take as the generating function not the square of the sum, but the product of the fractions $\frac{1}{1-x^p}$ (without casting out n when it is a prime), but this method would be inordinately more difficult to work with in computing series involving the roots of unity than the one chosen, which is in itself a felicitous invention.[1] Whether the method turns out successful or not, it at the very least gives an analytical expression for the number of ways of conjoining the mid-primes to make up $2n$ without trial, which in itself is a somewhat surprising result. Having lost my preliminary calculations, it may be some little time before I shall be able to say whether the method does or does not contain a proof of the new theorem; but that this can be ascertained, there is no manner of doubt. This is the first serious attempt to deal with Euler's theorem, or to bring the question into line with the general theory of partitions.

It is proper to regard the range 1 to $2n-1$ as consisting of two complementary flank regions, two lateral mid-prime regions, and a region reduced to a single term in the middle, as *ex.gr.*

1, 2, 3 : 4, 5 : 6 : 7, 8 : 9, 10, 11.

Or, again,

1, 2, 3 : 4, 5, 6 : 7 : 8, 9, 10 : 11, 12, 13.

And the question of $2n$ being resoluble into 2 primes breaks up into three, viz. whether $2n$ can be composed with two flank primes, two lateral mid-primes, or with the number in the central region repeated.

Some slight corrections are required in the preceding note in NATURE. P. 196, l. 5 of letter, for "improved method" read "original method"; l. 7, for "demonstration" read "denumeration"; l. 24, omit the words "with the exception of $2n = 2$." Also, p. 197, l. 3, for "$\rho\epsilon^{\phi}$" read "$\rho\epsilon^{i\phi}$."

January 1. J. J. SYLVESTER.

[1] For the generating function we may take any power greater than instead of the square, and the coefficient of x^{2n} will then be the number of couples making up $2n$ multiplied by $(r^2-r)\mu^{r-1}$, which can be calculated by the same method as for the square, but is more difficult and must give rise to numerous theorems of great interest, arising from the multiform representation of the same quantity.

Patterns produced by Charged Conductors on Sensitive Plates.

IN the course of a recent X-ray lecture demonstration, I accidentally got what is, so far as I know, a novel, and certainly an interesting result. Having taken a radiograph of three small wire skeletons enclosed in cardboard bodies, on the developed plate (covered with a plain glass pressed upon the film) being put into the lantern, I noticed the precipitated silver particles set themselves in certain lines. These radiated normally from the skulls and limbs of the figures, and in the more open parts of the background set themselves into a key or fret pattern. I concluded, on further examination, that this effect was probably due to a state of electric strain induced by the Röntgen tube, but it was only upon the softening of the gelatine film by the heat of the lantern that the particles were set free, so as to obey the electric impulse to which they were subjected.

This led me to experiment upon the effect produced by charged conductors on sensitive plates, with the final result of

securing very perfect images of the invisible electric discharge without the plates being exposed to either X-rays or light.

This discharge—or possibly, more strictly speaking, the electrified streams of air driven off by it—appears to act upon the plate exactly as light does. It is thus possible to secure impressions of such discharges by simple electrification and subsequent development.

FIG. 1.

Under certain conditions very perfect images of the relief upon coins and similar objects can be obtained. This seems to account fully for the fact that in some cases radiographs of coins have shown some trace of the design upon the under side which was in contact with the film.

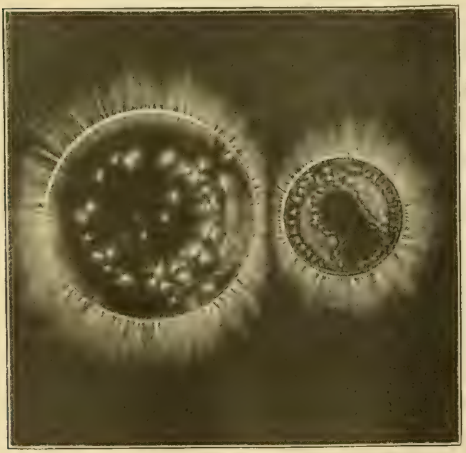

FIG. 2.

I enclose prints of the radiograph showing the set of the silver particles around the skeletons, which effect I have since reproduced, and also of what I think may properly be called electrographs of coins, and of discharges from metallic points and surfaces.

I should be glad to know if any similar results have come within the experience of any of your correspondents.

Fig. 1 is a radiograph of wire skeletons enclosed in cardboard figures, developed and fixed, covered with glass plate, and put in lantern. On the heat of the lantern softening the film, the precipitated silver particles set themselves in pattern. The explanation which suggested itself was that this was an electrical effect induced by the Röntgen tube, but I cannot definitely assert that this is the case. It is conceivable that the segregation of the particles may be due to some other play of forces, such as unequal tension in the film; but the first idea seems the most probable. I hope to test this further by experiment. I have reproduced a similar pattern, though not quite so perfectly as in this instance. The irregular edge is the result of the partial drying of the film.

Fig. 2 represents an aluminium medal and gold coin. The coins were laid upon a photographic dry plate, enclosed in a cardboard box, electrified for two seconds from one pole of a small induction coil, and developed. Brush discharge round margin very fine, the discharges from the two objects repelling each other. The larger was in high relief, and the lettering has produced small brush discharges. Some shaded ground in recessed part of coin, probably due to the electrified film of air, confined within the margin of the coin, resting in contact with the plate.

JAMES I'ANSON.

The Force of a Pound.

PROF. PERRY, in his review of my "Elements of Mechanics" in your issue of November 19, 1896, gives his method of explanation of mechanical units to engineering students.

The method is almost as perplexing as the one he so severely condemns. The source of confusion in both cases is in attaching the term "mass" to the ordinary gravitation system—the system of "weights and measures." Engineers have no need of the term; in its strict sense it is foreign to their work. The engineering unit of quantity is the "pound," as determined by the process of weighing against standard weights.

The engineer deals mainly with bodies at rest, or moving with uniform speed. The system sufficient for him is therefore not sufficient for the physicist, to whom the idea of acceleration is fundamental. The physicist notices that bodies possess a certain quality determinative of acceleration, and to this he gives the name *mass*. Masses are thus to be compared by kinetical methods, fundamentally at least. The term "mass" belongs to the system of the physicist, the so-called absolute system, and to it only.

To sum up. Use the term weight in its legal sense, which is that understood by the engineer and by people in general; define mass with reference to acceleration, and not as "quantity of matter"; understand that the passage from an absolute to a gravitation system [not from mass to weight] is by means of a suitable factor with a corresponding change of unit, and all confusion vanishes.

The agitation in favour of an absolute system involving the "poundal" should be discouraged for the reason, among others, that the adoption of the metric system is delayed in consequence. The metric system alone is sufficient for both engineer and physicist.

T. W. WRIGHT.

Schenectady, N.Y., December 17, 1896

Acceleration.

IN NATURE, No. 1415, p. 125, Prof. Lodge asserts that the subject of acceleration is at the root of the perennial debate between engineers and teachers of mechanics; and he urges clearness of idea and accuracy of speech on all who deal with the junior student. Towards this end I would suggest that the too common phrase "acceleration of velocity" should be abandoned when the idea intended is "velocity of velocity." V and V ought not to be confounded. Let the student be told that the time-rate of change of a particle's speed in any given *fixed* direction at a given instant is called the acceleration of the *particle* in the given direction at the given instant. If the direction of the particle's motion at the given instant makes an angle θ with the given fixed direction L, and if the speed of the particle in its own direction at this instant is V, its speed in the direction L is V cos θ. The time-rate of change of this is called the acceleration of the *particle* in the direction L. It is $[\dot{V}\cos\theta - V\dot{\theta}\sin\theta]$ units of speed per unit of time. If $\theta = 0$, L coincides with the line of motion, hence the acceleration of a particle along its line of motion is $\dot{V}$ units of speed per unit of time. If $\theta = \frac{1}{2}\pi$, L coincides with a normal, hence the acceleration of the particle along a normal is $V\dot{\theta}$, *i.e.* it is the product of the linear speed and the angular speed. Linear speed is expressed in units of length per unit of time; angular speed is expressed in units of angle per unit of time. Acceleration is expressed in units of speed per unit of time. EDWARD GEOGHEGAN.

Bardsea.

THIS is simply kinematic, and well known; but perhaps its adduction at the present time is useful as emphasising the fact that acceleration in general is not a ludicrously simple and obvious idea. The term "velocity" is, however, hardly a good synonym for "rate of change" of everything: the term "fluxion" would be better; moreover, none of the phrases about "units" are necessary. O. J. L.

The Rydberg-Schuster Law of Elementary Spectra.

THE interesting law of connection shown so clearly by Prof. Schuster in the recent pages of NATURE (vol. lv. p. 200, and p. 223), to exist between the primary and secondary series of lines in the representations given by Kayser and Runge of the spectra of certain metallic elements, is a law which seems so suggestive of the musical phenomena termed in acoustics "difference-tones," as a possible explanation of its origin, that it may perhaps be of some use in seeking for a true account of the connection, to show here how it may be held, if not quite perfectly and exactly, at least up to a certain point of great resemblance, to possess that aspect.

The set of fundamental and over agitation-rates comprised in a Balmer-series, form a sort of chime of rays together, perhaps not very unlike the mixture of notes composing the almost vocal-sounding scream, or buzz, rather than a pure note, which a humming-top emits. From combined actions of the proper members of this chime, sets of vibrations would no doubt arise, with oscillation-rates in a succession of secondary series, equal to the surplus rates of all the succeeding proper members of the chime above the oscillation-rate of some starting member. In the case of Balmer's series, $n \frac{1}{\lambda} = A\left(1 - \left(\frac{2}{m}\right)^2\right)$, the differential set for all the vibration-rates following the first, or fundamental rate, $n_1 = A\left(1 - \left(\frac{2}{3}\right)^2\right)$, is represented generally by

$$n'_1 \quad A\left|\left(1 - \left(\frac{2}{m}\right)^2\right) \left(1 - \left(\frac{2}{3}\right)^2\right)\right| \quad \left|\left(\frac{2}{3}\right)^2 \left(\frac{2}{m}\right)^2\right|;$$

or $n'_1 = \left(\frac{2}{3}\right)^2 A\left(1 - \left(\frac{3}{m}\right)^2\right)$, a slightly modified Balmer-series, of which the convergence frequency,

$$\left(\frac{2}{3}\right)^2 A, \text{ is } = A - A\left(1 - \left(\frac{2}{3}\right)^2\right),$$

or the excess of the primary series' convergence frequency, A, above its fundamental rate of vibration, $A\left(1 - \left(\frac{2}{3}\right)^2\right)$; the law of dependence of the secondary on the primary series found to hold good in a number of line-spectra of the elements, by Prof. Schuster and Prof. Rydberg. But the form of the second series is a little different from that of the first, in that the coefficient of its second term is nine times instead of four times the fixed value of the first term. I regret that I am not familiar enough with the measurements obtained, and with the very important discussions that have been based upon them, to be able to say if any secondary series of this modified form, or of the similar higher forms, as $n'_2 = \left(\frac{1}{2}\right)^2 A\left(1 - \left(\frac{4}{m}\right)^2\right)$, &c., are met with in the ranks of lines found by Kayser and Runge to accompany the chief, or leading ranks in so many of the spectra of the elements. But as a supposition which seems thus to present itself most prominently and invitingly for trial and consideration, I would yet venture to suggest that real or actual productions of secondary rays by differences of rates of vibration among primary rays, may perhaps occur in molecules in some such way as that recently expounded by Prof. Everett[1] to account for the corresponding phenomenon of audition of difference-tones in acoustics without excluding those tones as purely subjective existences from a real place in physics. If the possibility of such secondary, differential light rays' origination from primary vibrations in molecules is admissible, then this present description of their long secondary, tertiary and other higher ranks or scales of vibration-rates, may perhaps prove a means (with some transformations very possibly not quite inexplicable, in the least complicated cases) of comprising all the secondary ranks' array of vibration-frequencies, and the surprisingly exact law of numerical dependence shown so very certainly and clearly by Prof. Schuster to hold between the primary and secondary ranks' terminal oscillation-rates, in one view of physical relationship together. A. S. HERSCHEL.

Observatory House, Slough, January 9.

P.S.—The answer to this suggestion is, I see, supplied already by Prof. Schuster in his first letter on this newly-found relationship; for he has there noted (this vol., p. 201), that the above supposed successive differences, although their series, $A'\left(1 - \left(\frac{3}{m}\right)^2\right)$, is of the type $A - \frac{B}{m^2}$, only approach to, without exactly reproducing the set of frequencies of the subordinate spectrum-series. If $A - \frac{B}{3^2}$ represents the lowest or "fundamental" rate of vibration, F, in all the primary line-series, and therefore $\frac{B}{3^2} = A - F$ the "convergence frequency," A', common, by the observed law, to both the line-series subordinate to such a primary one, then whatever values, near 4, B may have been found to have in the chief series, the first of the above ideal series of differences may easily be seen to be always $A'\left(1 - \left(\frac{3}{m}\right)^2\right)$; and this does not correspond more than approximately, except in rays of frequencies very near to the "convergence-value."

Sailing Flight.

ALL students of aerodynamics must be sorry to learn of the death of Herr Lilienthal, on August 11 last. His loss is serious, as he evidently had the courage necessary to put these exceptionally dangerous experiments to practical test, which few care to do, and had thereby gained a large experience.

I have just secured a Cyrus (*Grus antigoni*), 5 feet 2 inches in height. It weighs 16 pounds, and has a spread of wings 8 feet 8 inches.

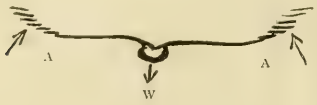
The primary feathers require 10 ounces each to bend them to the curve seen when the bird is soaring; they are 17 inches long on the feathered portion, not all identical in size or strength, but their total comes so nearly to the weight of the bird, that it is obvious the primary feathers constitute the lifting mechanism.

From the almost universal arrangement of the mode of support in relation to the weight, as seen amongst birds, bats, and

[1] *Proceedings* of the Physical Society of London, vol. xiv. p. 93; and *Philosophical Magazine*, March 1896.

fish, &c., I cannot help thinking that Lilienthal's central and superposed aeroplanes were a mistake; and that instead of that type, while the weight must be central, the sustaining aeroplanes should, like the birds, have great lateral extension.

You will observe in the diagram that the wing planes can each be divided into two portions, having quite distinct functions. The outer extremities are the sustaining aeroplanes, marked by the arrows, while the inner portion of each wing, A to W, is that which assists the bird when it is alighting, by offering a fixed passive resistance to a fall when the speed is slackened down. W is the central weight.



Observe also that in the bird, the sustaining mechanism is so far structurally subdivided that the loss of a primary feather is not fatal to flight; each primary lies, and acts, in a distinct plane, and has its attachment distinct from the others.

Now, it seems to me that Mr. Maxim's central aeroplane and twin screws, situated so far apart, are hardly a safe plan, for if accident happen to one screw, the other must at once stop, and the whole thing, *nolens volens*, come down.

It is not like the twin-screw steamer, where the water sustains the hull, and progress by one screw is still possible. In the aerial ship translation is the support, and it only.

In the bird, when sailing, we see no screw at work; the aeroplanes are there plain enough, lifting the 16-pound bird higher and higher as we watch it; but propeller there is none.

This propulsion, as I before stated, must be got from an outside source. The bird can only soar *in a wind*, and then, to rise, must go in spirals, passing to leeward a little at each lap. Of course the wing planes are not horizontal, but inclined thus in

passing round the centre of spiral C; and there is necessarily great centripetal reaction at such a high speed of translation as fifty or sixty miles per hour.

I think Mr. Maxim will find the bird arrangement of aeroplanes to weight, and a central screw, the best and safest. If a large central overhead aeroplane is needed, it would be for safety in alighting only. S. E. PEAL.

Sibsagar, Asam, December 13, 1896.

OSMOTIC PRESSURE.

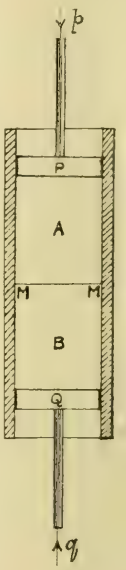
IN last week's NATURE, Lord Rayleigh gave, *for an involatile liquid*, a rigorous and clear proof of "the Central Theorem" of osmotics. But this theorem, though highly interesting in itself, is not, so far as I can see, useful as a guide for experiment. Consider for example the typical cases of sugar, and of common salt, dissolved in water.

If water were absolutely non-volatile, the osmotic pressure of each solution against an ideal semi-permeable membrane separating it from pure water, would, according to the theorem, be equal to the calculable pressure of the ideal gas of the dissolved substance supposed alone in the space occupied by the solution. *This would be true whatever be the molecular grouping of the sugar or of the salt in the solution.* It is believed that experiment has verified the theorem, extended to volatile solvents, as approximately true for sugar and several other substances of organic origin, and of highly complex atomic structure; but has proved it to vastly under-estimate the osmotic pressure for common salt and many other substances of similarly simple composition. KELVIN.

Belfast, January 19.

ON OSMOTIC PRESSURE AGAINST AN IDEAL SEMI-PERMEABLE MEMBRANE.[1]

To approach the subject of osmotic pressure against an ideal impermeable membrane by the easiest way, consider first a vessel filled with any particular fluid divided into two parts, A and B, by an ideal surface, MM. Let a certain number of individual molecules of the fluid in A, any one of which we shall call D (the dissolved substance), be endowed with the property that they cannot cross the surface MM (the semi-permeable membrane); but let them continue to be in other respects exactly similar to every other molecule of the fluid in A, and to all the molecules of the fluid in B, any one of which we shall call S (the solvent), each of which can freely cross the membrane. Suppose now the containing vessel and the dividing membrane all perfectly rigid.[2] Let the apparatus be left to itself for so long time that no further change is perceptible in the progress towards final equilibrium of temperature and pressure. The pressures in A and B will be exactly the same as they would be with the same densities of the fluid if MM were perfectly impermeable, and all the molecules of the fluid were homogeneous in all qualities; and MM will be pressed on one side only, the side next A, with a force equal to the excess of the pressure in A above the pressure in B, and due solely to the impacts of D molecules striking it and rebounding from it.



If now, for a moment, we suppose the fluid to be "perfect gas," we should find the pressure on MM to be equal to that which would be produced by the D molecules if they were alone in the space A; and this is, in fact, very approximately what the osmotic pressure would be with two ordinary gases at moderate pressures, one of which is confined to the space A by a membrane freely permeable by the other. On this supposition the number of the S molecules per unit bulk would be the same on the two sides of the membrane. And if, for example, there are 1000 S molecules to one D molecule in the space A, the pressure on the piston P would be 1001 times the osmotic pressure, and on Q 1000 times the osmotic pressure. But if the fluid be "liquid" on both sides of the membrane, we may annul the pressure on Q and reduce the pressure on P to equality with the osmotic pressure, by placing the apparatus under the receiver of an air-pump, or by pulling Q outwards with a force equal and opposite to the atmospheric pressure on it. When we do this, the annulment of the integral pressure of the liquid on the piston Q is effected through balancing by attraction, of pressure due

[1] Communicated to the Royal Society of Edinburgh, January 18, by Lord Kelvin.

[2] In the drawing, the vessel is represented by a cylinder closed at each end by a piston to facilitate the consideration of what will happen if, instead of supposing it rigid, any arbitrary condition as to the pressures on the two sides of the membrane be imposed.

to impacts, between the molecules of the liquid S and the molecules of the solid piston Q. We are left absolutely without theoretical guide as to the resultant force due to the impacts of S molecules and D molecules striking the other piston, P, and rebounding from it, and their attractions upon its molecules; and as to the numbers per unit volume of the S molecules on the two sides of MM, except that they are not generally equal.

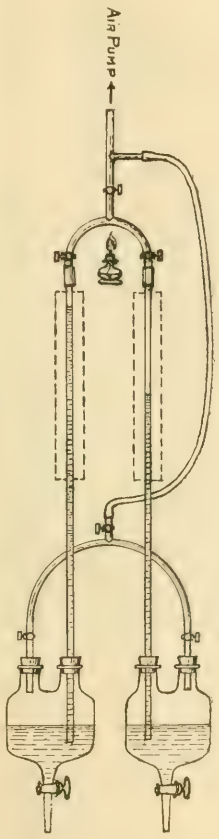
No molecular theory can, for sugar or common salt or alcohol, dissolved in water, tell us what is the true osmotic pressure against a membrane permeable to water only, without taking into account laws quite unknown to us at present regarding the three sets of mutual attractions or repulsions: (1) between the molecules of the dissolved substance; (2) between the molecules of water; (3) between the molecules of the dissolved substance and the molecules of water. Hence the well-known statement, applying to solutions, Avogadro's law for gases, has manifestly no theoretical foundation at present; even though for some solutions other than mineral salts dissolved in water, it may be found somewhat approximately true, while for mineral salts dissolved in water it is wildly far from the truth. The subject is full of interest, which is increased, not diminished, by eliminating from it fallacious theoretical views. Careful consideration of how much we can really learn with certainty from theory (of which one example is the relation between osmotic pressure and vapour pressure at any one temperature) is exceedingly valuable in guiding and assisting experimental efforts for the increase of knowledge. All chemists and physicists who occupy themselves with the "theory of solutions," may well take to heart warnings, and leading views, and principles, admirably put before them by Fitzgerald in his Helmholtz Memorial Lecture (*Transactions* of the Chemical Society, 1896) of January 1896 (pages 898–909). KELVIN.

METHOD FOR MEASURING VAPOUR PRESSURES OF LIQUIDS.[1]

Apparatus for realising the proposed method is represented in the accompanying diagram. Two Woolfi's bottles, each having a vertical glass tube fitted air-tight into one of its necks, contain the liquids the difference of whose vapour pressures is to be measured. Second necks of the two bottles are connected by a bent metal pipe, with a vertical branch for connection with an air pump, provided with three stopcocks, as indicated in the diagram. Each bottle has a third neck, projecting downwards through its bottom, stopped by a glass stopcock which can be opened for the purpose of introducing or withdrawing liquid. The upper ends of the glass tubes are also connected by short india-rubber junctions with a bent metal pipe carrying a vertical branch for connection with an air-pump. This vertical branch is provided with a metal stopcock.

To introduce the liquids, bring open vessels containing them into such positions below the bottles that the necks project downwards into them. Close the glass stopcocks of these lower necks, open all the other six stopcocks, and produce a slight exhaustion by a few strokes of the air-pump. Then, opening the glass stopcocks very slightly, allow the desired quantities of the liquids to enter, and close them again. They will not be opened again unless there is occasion to remove the whole or some part of the liquid from either bottle; and, unless explicitly mentioned, will not be included among the stopcocks referred to in what follows. It will generally be convenient to make the quantities of the two liquids introduced such, that they stand at as nearly as may be the same levels in the two bottles, as indicated in the drawing.

Operation No. 1.—Close the stopcock on the lower passage from the bottles to the air-pump (which, for brevity, we shall call the lower air-pump stopcock); and, with the other five stopcocks all open, work the air-pump till the liquid in one of the glass tubes rises to within a centimetre of the india-rubber collar round its top.



Operation No. 2.—Open the lower air-pump stopcock till the liquids fall down the tube, nearly down to hydrostatic equilibriums in the bottles. Close it again, and work the air-pump till the liquid in one of the glass tubes rises to within a centimetre of the india-rubber collar.

Operation No. 3.—Repeat operation No. 2 over and over again until you cannot, however long you go on pumping, get the liquid in either tube to rise within a centimetre of the india-rubber collar.

Operation No. 4.—Continue Operation No. 3 until the

[1] "On a Differential Method for Measuring Differences of Vapour Pressures of Liquids at One Temperature and at Different Temperatures." (Communicated to the Royal Society of Edinburgh, January 18.) By Lord Kelvin, G.C.V.O.I.

liquid that rises higher than the other stands steadily at a convenient marked point, when the air-pump is kept vigorously going, with the lower air-pump stopcock closed. This marked point may be perhaps a few centimetres below the india-rubber collar, so as to allow the liquid surface of it to be conveniently seen through a wide glass cylinder containing hot or cold water around it, applied to fulfil the thermal conditions referred to in Operation No. 6. In these present circumstances the vapour pressure is practically equal throughout the upper bent tube, and the portions of the glass tubes between its ends and the liquid surfaces in the two glass tubes. Hence the more volatile of the two liquids is kept cool at its surface by rapid evaporation, and the less volatile liquid is kept warm by rapid condensation of vapour into it, so that, by flow of vapour through the bent tube, the difference of temperatures required to equalise the vapour pressures is very nearly maintained.

Operation No 5.—Close the upper three stopcocks, both air-pump stopcocks being already closed, and the two lowest metal stopcocks open. Leave the apparatus to itself until the temperatures become equalised. The difference of levels of the liquids in the two glass tubes, with proper corrections for their densities and for the difference, if any, of levels of the liquid surfaces in the two bottles, measures accurately the difference of vapour pressure over them, at the temperature to which they become equalised.

Operation No. 6.—Open the upper air-pump stopcock, work the air-pump and open the stopcock over the top of one of the two liquids for a minute or two and close it again. Do the same for the other liquid. Allow temperatures to be equalised to what they were at the end of Op. 5. If any air or other foreign volatile substance[1] has escaped from either liquid along with its proper vapour, its level will be seen higher than it was at the end of Op. 5. The present operation (No. 6) must be continued long enough to distil out of either, or both liquids, any such foreign ingredients if, when originally introduced, any such impurity was contained.

Operation No. 7.—By proper thermal appliances, indicated by the dotted lines in the diagram, and the lamp under the upper bent metal tube (inserted merely as an indication that somehow the metal tube is to be always slightly warmer than the warmer of the two liquid surfaces, in order that there may be no condensation of vapour in it), bring the upper surfaces of the liquids to any other temperature, or to two different temperatures. The difference of levels of the liquids in the two tubes, with proper correction for the densities of the two liquids at their actual temperatures in different parts of their columns, gives the difference of vapour pressures for the actual temperatures of the two liquids at their upper surfaces.

Operation No. 8.—To facilitate and approximately determine the hydrostatic correction for specific gravities at the actual temperatures of the two liquids, open wide the stopcocks above the tops of the two glass tubes, and let a little air run back from the air-pump, by very cautiously and slightly opening our upper air-pump stopcock, and closing it again before the lower of the two liquid surfaces reaches the lower end of its glass tube. After that, by cautiously opening and closing our lower air-pump stopcock, let in a little air to the bottles until the mean level of the liquids in the two columns rises to nearly the same level as it had in the measured positions of Op. 5 or Op. 6. In the present circumstances, air in the upper bent metal tube resists diffusion of vapour through it sufficiently to prevent any important difference of temperatures from being produced by evaporation and condensation at the two liquid surfaces, and there is practically perfect hydrostatic equilibrium of equal liquid pressures at the tops of the two columns.

The vapour pressure of water is accurately known through a very wide range of temperature from Regnault's experiments; hence, if pure water be taken for one of our two liquids, the mode of experiment described above determines the vapour pressure of the other liquid.

The apparatus may be kept day after day with the same liquids in it (all the stopcocks to be closed, except when it is not in use for observations); and thus, the observations for difference of vapour pressures may be repeated day after day; or a long series of observations may very easily be made to determine vapour pressures at different temperatures. Always before commencing observations, Operation 6 must be repeated to remove air or other impurity, if any air has leaked in, or if air or other foreign volatile impurity has escaped from dissolution in either liquid into the vapour space above it. KELVIN.

[1] See Ostwald, "Physico-Chemical Measurements," translated by Walker (Macmillan, 1892), last paragraph, page 112.

RELATIVE TEMPERATURES IN GEISSLER TUBES.

IN the Physical Institute of the Berlin University, Mr. R. W. Wood has been making a series of experiments, most interesting to students of astrophysics, with the object of investigating the relative temperatures at different parts of the discharge in a Geissler tube, with special reference to the stratification phenomena. Wiedemann and Hittorf, and also the theoretical calculations of Warburg, have shown that the temperature of the gas in the positive part of the discharge lies far below red heat, while that of the negative light, according to Hittorf, is at least below the melting-point of platinum. These observations are for the most part corroborated by the experiments of Mr. Wood, who has investigated in this case a fixed part of the discharge in an atmosphere of nitrogen under varying pressures and currents of different strengths. The results obtained by employing hydrogen instead of nitrogen established the fact that, under similar conditions of pressure and strength of current, the heating was only about 11 per cent. of that found in the former case. It was found difficult, however, to keep a steady current with this gas.

Perhaps more interesting are the results which he has been able to procure by determining the relative temperatures of the different parts of the space between the anode and kathode. For this he has designed a neat and very simple means, by which the positions of the bolometer inside the vacuum tube might be varied at will without impairing in the least degree the vacuum. The description of this apparatus will be found in the article in which the results of his observations have been published (*Physical Review*, November–December 1896, xxi.). We may, however, mention that the bolometer wire—that is, the wire which was placed in the different positions between the two poles of the Geissler tube to indicate the varying temperatures of the different parts of the discharge—was here composed of platino-iridium, and bent in the form of a loop. Its exact position could at any moment be read off from a vertical scale. It was thus found possible to make a complete map of the temperature changes inside the vacuum tube.

In the *unstratified* anode light the temperature was sometimes constant for the greater part of the column, rising to a maximum near the middle, and falling off as the dark space was approached. The maximum was always found when the light was on the point of stratifying, and sometimes at higher pressures. The exact conditions, however, could not be determined; but the extent of the anode light played an important part.

On nearing the dark space, a decrease of temperature was always observed. The temperature was found to drop very suddenly on leaving the anode light, reaching a minimum near the middle of the dark space ; a rapid rise to maximum occurred as the blue negative light was entered. With a pressure sufficiently reduced to cause the appearance of *stratifications* in the anode light, the maximum was always to be found in the middle of the column, the temperature rising as the anode was left behind, and falling after the middle of the column was passed. In addition, "there is a periodic rise and fall, the light discs being warmer than the dark spaces between them, although one often finds a point where there is no change of temperature on passing from a light space to a dark." This last-mentioned fact is explained on the ground that the increase in the steepness of the curve as the maximum is approached, masks the comparatively small decrease due to the passage from the light to the dark interspaces.

One of the many diagrams he reproduces, shows the temperature fluctuations in the stratified discharge at a low pressure of 0·1 mm. The ordinates increase for a rise in temperature, and the abscissæ are longer the further the bolometer wire is away from the anode. The horizon of the diagram is taken as the temperature of the room, which in this case was 25°. Comparing the curve giving the fluctuations of the bolometer wire placed at points of different intensities throughout the tube (the latter being drawn parallel to the abscissæ), many points of interest may be at once seen. Commencing at the anode, the curve on the whole is fairly horizontal, but rises wave fashion at every increase of luminosity in the tube, dropping more or less suddenly as a dark space is entered. As the kathode is approached, the bolometer wire enters the large dark space ; the curve falls somewhat abruptly down for some distance, rising again rapidly as the kathode is approached.

It may be stated that the maximum in the anode light is less predominant here than it is at higher pressures, owing to the smaller changes of temperature.

The periodic change in the stratified anode light was made the subject of a detailed investigation, more points of reference being taken. These results were also plotted in the diagram just mentioned (larger scale). "The temperature is steady for a certain distance, then rises gradually to a maximum, situated in the brightest part of the disc, turns and drops suddenly as we pass out of the sharply defined edge of the disc. The difference of temperature between the light and dark spaces varies from 0°·5 to about 1°·5, depending on the degree of exhaustion and current strength."

Assuming the electrical energy is wholly connected with heat, the temperature curves indicate for

Positive light ...	Medium	potential fall ..	Medium temperature
Dark space ...	Small	,, ,, ...	Low ,,
Negative light ...	Large	,, ,, .	High ,,

a result which, as Mr. Wood says, agrees with what is already known.

Two incidental points of interest mentioned refer to the behaviour of the strata. The movement of the bolometer loop from one stratum to another appears, at some pressures, to draw the stratum through which it is passing into the one immediately below it, the two dissolving into one, and the place left thus vacant being filled up by a new stratum springing off the anode. The edges of these strata further act as if they "had an elastic skin or a sort of surface tension, bending in as the wire pushes against them, and finally snapping back to their original positions, leaving the wire well within the luminous disc." Mr. Wood, commenting on the results, considers that the curves obtained with the movable bolometer indicate with considerable accuracy the relative temperatures in the different parts of the discharge.

THE TOMB OF LOUIS PASTEUR.

AN account of the impressive ceremony with which the remains of Pasteur were laid in their last resting-place at the Pasteur Institute was given in these columns on December 31, 1896. We are indebted to the *Lancet* of January 9 for the following full description of the tomb, and for the accompanying illustration, which is reproduced from a fine picture of the mausoleum of the great French investigator.

The mausoleum is built at the end of a long corridor in the Institute, and is shut off by magnificent gates of wrought iron.

Before describing it, it is interesting to note that it was built by the Pasteur family, and Monsieur J. B. Pasteur, the son of the great *savant*, suggested as a model the well-known tomb of Galla Placidia at Ravenna, which he had visited in the course of his travels in Italy.

This tomb was built about 440 by the Christian Empress Placidia, the daughter of Thedosius the Great. It is in the form of a Latin cross 49 feet long and 41 feet broad, and we may refer to it in some detail to show how it inspired the architect of Pasteur's tomb, Monsieur Girault. The interior of Placidia's tomb is covered by mosaics, on a blue ground. Above the entrance are garlands of fruit and foliage ; and in the dome the symbols of the Evangelists. In the four arches which support the dome are figures of eight apostles, and between them is seen the familiar representation in mosaics of doves drinking out of a vase. Under the vaulting of the right and left transept are the other apostles, and, between them, stags drinking at a spring in the midst of golden foliage. There are also designs in mosaic of branches of vines ; and two subjects, full of grace and dignity, the *chef-d'œuvres* of Christian art in the fifth century, the first representing the Good Shepherd with His sheep, and the second representing the triumph of the Christian faith. The altar is constructed of oriental onyx, and behind it is the large marble sarcophagus, which was at one time enriched with plates of silver.

Turning now to the Pasteur mausoleum, we find the archway

over the gates decorated in mosaic with irises on a gold ground, and there is also the simple inscription—"*Ici repose Pasteur*," and on either side of it the dates of his birth and death—1822–1895. Passing through the gates, the crypt is approached by a flight of nine steps of white statuary marble. The pavement of the crypt is of marble mosaic, on which are represented large wreaths of laurel. The crypt is formed by four arches which support a cupola, and in the centre is placed the sarcophagus, which is carved out of a single block of dark-green porphyry. The arches are supported on four groups each of three columns, two of green porphyry and one of red, with Byzantine capitals of white marble. The walls of the crypt are lined with pavonazza, a cream-coloured marble richly veined in black, and above it are beautifully executed mosaics. On the marble which fills the arches on the right and left are inscriptions indicating Pasteur's discoveries in historical order as follows :—

1848. Dyssymétrie Moléculaire.	1871. Études sur la Bière.
1857. Fermentations.	1877. Maladies Virulentes.
1862. Générations dites Spontanées.	1880. Virus Vaccins.
1863. Études sur le Vin.	1885. Prophylaxie de la Rage.
1865. Maladies des Vers à soie.	

Beyond the sarcophagus is an apsidal chapel containing an altar of white marble enclosed by a balustrade of the same material. Above the staircase is the following inscription from the oration delivered at the reception of Pasteur into the Academy of Science : "Heureux celui qui porte en soi un dieu, un idéal de beauté, et qui lui obéit—idéal de l'art, idéal de la science, idéal de la patrie, idéal des vertus de l'Evangile." In the apse is another inscription containing the name of the architect and other interesting particulars : "Ce monument fut élevé en MDCCCXCVI. à la mémoire de Pasteur par la piété de sa veuve et de ses enfants. Charles Louis Girault composa l'architecture et la décoration ; il dirigea les travaux. Luc Olivier Merson dessina les figures de la coupole. Auguste Guilbert Martin exécuta les mosaïques."

In the mosaics are representations of fowls, cattle, sheep, and dogs, indicating Pasteur's researches on chicken cholera and attenuation of virus, on anthrax, on *clavelée* or sheep pox, and on rabies. There are also beautiful designs of hops, vines, and mulberry trees with silkworms and moths, illustrating respectively his researches on the so-called diseases of beer and wine and on the silkworm disease. Pasteur was a devout Roman Catholic, and the religious side of his character is indicated in the mosaics by angelic figures of Faith, Hope, Charity, and Science, and, above the altar, by the figure of a dove descending, representing the Holy Spirit, and on either side the Greek letters A and Ω. At the top of the cupola, light is admitted through slabs of oriental onyx.

Such is the magnificent resting-place of Louis Pasteur, and it was a happy idea that this tomb should be placed where his successors carry on his great work, and where students from all parts of the world may be reminded of the example he set of a life of untiring devotion to science and humanity.

NOTES.

THE new Session of Parliament began on Tuesday. From the forecast of legislative business contained in the Queen's Speech, it appears that the most stringent measures are being taken for the eradication of plague at Bombay and Karachi. Against this declaration attention may very well be called to foreign complaints of English apathy in the matter. Prof. Drasche, of Vienna, member of the Supreme Sanitary Council, complains that England has not shown the least interest in adopting any code of regulations for dealing with the plague and confining it within narrow limits ; and the Paris press are protesting against our carelessness and neglect of effective precautionary measures. Another item in the Queen's Speech refers to education. A measure for the promotion of primary education will be brought in ; and, if time permits, further proposals for educational legislation will be considered. A Bill for the establishment of a Board of Agriculture in Ireland will also be introduced.

PROF. DR. PAUL HARZER, Director of the Observatory at Gotha, has been appointed Director of the Observatory at Kiel, and professor of astronomy in the University there, in succession to the late Prof. Krüger. The Gotha Observatory was founded at the beginning of this century, and has numbered among its directors Encke, Hansen, Krüger, Seeliger, and Becker.

THE German Emperor and Empress visited the Polytechnic Institute at Charlottenberg on Tuesday in last week, and were present at a lecture delivered by Prof. Linde on the "Liquefaction of Air." His Majesty conferred upon Prof. Linde membership of the Second Class of the Order of the Crown.

DURING the nine months which have elapsed since the last public announcement, considerable progress has been made with the work of the Huxley Memorial Committee. The full-sized model for the statue, on which Mr. Onslow Ford, R.A., is engaged, is well advanced, and will shortly be completed ; and the Trustees of the British Museum of Natural History, at South Kensington, have accepted the offer of the statue itself, which will be executed in marble, and ultimately placed in the central hall of that institution, near the statue of Darwin. The design for the Royal College of Science medal has been obtained by prize competition among persons resident in Great Britain and Ireland, and the selection has fallen upon the design of Mr. L. Bowcher, who has produced a highly successful work of art, and is now engaged upon the dies. The amount promised and received is now about 2900*l.*, over 600*l.* having been subscribed since progress was last reported in the public press. Subscription has been largely promoted by local institutions and scientific societies in various parts of the world. Bristol, Leeds, Leicester, Adelaide, Sydney, New Zealand, and Calcutta have been conspicuous by their aid ; British Guiana, Cairo, the East Indies, and Mauritius have contributed ; and welcome support has been received from the United States of America, from France, Germany, Austria-Hungary, Holland, Belgium, and Switzerland, Scandinavia, Italy, Portugal, Russia, and Servia, from Mexico and Peru, and from Arabia and Japan. Aid is expected from other centres, both at home and abroad ; and the nature of any additional memorial yet to be decided upon must largely depend upon the amount still to be subscribed. In consideration of the world-wide support which the memorial has received, it is hoped that it may be possible to secure a form of memorial in which persons of all nationalities shall participate. Donations may be sent to the Treasurer, Sir J. Lubbock, or the bankers, Messrs. Robarts, Lubbock, and Co. (15 Lombard Street, E.C.), or to the Hon. Secretary, Prof. G. B. Howes (Royal College of Science, South Kensington, S.W.).

THE New York Academy of Medicine will celebrate the jubilee of its foundation on January 29.

SIR W. MARTIN CONWAY will describe his expedition across Spitzbergen, on Monday next, January 25, at a meeting of the Royal Geographical Society.

IT is with great regret that we announce the death on Sunday morning, January 10, of Kristian Bahnson, the distinguished ethnologist, of Copenhagen. He had accomplished much, and gave promise of valuable work in the future.

THE *Times* correspondent at Teheran reports that a severe earthquake occurred at the island of Kishm, in the Persian Gulf, on January 11, causing enormous loss of life.

THE University of Catana has been presented with the Island of Cyclops, off the coast of Sicily, by Signor Gravina. The island is only a kilometre in circumference, but its configuration is peculiar, and the centre is about one hundred metres above sea-level. It is proposed to construct upon the island a laboratory for investigations in zoology and pisciculture.

THE scientific expedition organised by the German Government to study the economic and industrial conditions and possibilities in the Far East will probably start from Bremen on January 27, on board the North German Lloyd steamer *Sachsen*. The nature and scope of the investigations to be undertaken have been discussed and settled at a recent meeting at the Ministry of the Interior.

AT the twenty-fourth annual dinner of the Old Students of the Royal School of Mines, to take place on Tuesday, January 26, at 7 p.m., at the Criterion, the chairman will be Dr. T. K. Rose. Profs. Judd, Perry, Rücker, Tilden, Howes, Farmer, Roberts-Austen, and Le Neve Foster have promised to be present; and amongst other guests may be mentioned Sir G. G. Stokes, Bart., Sir Frederick Abel, Bart., Mr. Windsor Richards (President of the Institution of Mechanical Engineers), and Dr. Hicks (President of the Geological Society).

ON the 28th inst. Prof. James A. Ewing will commence, at the Society of Arts, a course of six Howard Lectures on "The Mechanical Production of Cold." The Howard Lectures were founded on a bequest by Thomas Howard, in 1872, who left a sum of money for a prize to the author of a treatise on "Motive Power or its Applications." The lectures are given at intervals, as the accumulations of the fund permit, and are afterwards published in book form. Courses have been delivered by Sir William Anderson, on "The Conversion of Heat into Useful Work," and by Prof. Unwin, on "The Development and Transmission of Power."

THE Franklin Institute of Philadelphia announces the award of the following John Scott Legacy Medals and Premiums:—William S. Burroughs, of St. Louis, for his calculating machine; Émile Berliner, of Washington, for his gramophone; Edward Brown, of Philadelphia, for improvements in pyrometers; Dr. W. C. Röntgen, for his investigation of a new kind of rays; Dr. Elisha Gray, for his telautograph; Pedro G. Salom and Henry G. Morris, of Philadelphia, for their automobile vehicle. The Elliott-Cresson Medal has been awarded to Hamilton Y. Castner, of Oldbury, for his electrolytic process for caustic and bleach.

THE International Exposition to be held at Brussels this year will comprise a Science Section divided into seven classes, viz. mathematics and astronomy, physics, chemistry, geology and geography, biology, anthropology and bibliography. Various advantages are offered to exhibitors, among them being space free of charge, and reduction of rates for the transport of the exhibits. In connection with this Exposition, the Belgium Government offers prizes, amounting in the aggregate to twenty thousand francs, for the best solutions of a number of scientific problems, a list of which can be obtained from M. Van Overloop, 17 rue de la Presse, Bruxelles. Objects and memoirs intended for competition or exhibition should be sent in before the middle of April.

WE regret to record the death of Dr. F. J. Mouat, formerly Professor of Chemistry and Materia Medica, at Calcutta, and Chemical Examiner to the Government of India. He was a Fellow of a number of British learned Societies, and member of the Senate of Calcutta University. We also have to announce the deaths of Dr. W. Deecke, of Muhlhausen, one of the foremost authorities upon ancient Etruria and the Etruscans; General Francis A. Walker, President of the Massachusetts Institute of Technology; Prof. W. H. Pancoast, President of the Medico-Chirurgical College in Philadelphia: Dr. Theodore G. Wormley, Professor of Chemistry and Toxicology in the University of Pennsylvania; Dr. F. Buka, Professor of Geometry in the Technical High School at Charlottenburg; and Dr. Josef von Gerlach, Professor of Anatomy in the University of Erlangen.

FOLLOWING the example of the Institution of Civil Engineers, the Society of Civil Engineers of France has built itself a magnificent house, which was opened with great ceremony, on January 14, by the President of the French Republic. A large number of guests were present at the soirée, including representatives of the various French technical societies. The only English society represented was the Iron and Steel Institute, who sent Prof. Roberts-Austen. The new building, which is situated in the Rue Blanche, Paris, was designed by M. F. Delmas, and was erected in 262 days. It comprises in the basement engine-rooms and store-rooms, on the ground floor the meeting-room, on the first floor reception-rooms for the members, on the second floor the secretary's offices and the council-room, and on the third floor the library. Access to the various floors is obtained by means of an electric lift. The meeting-room contains seats for 500 persons, and the floor is so arranged that it may be horizontal for receptions, or inclined so as to convert the room into an amphitheatre for the meetings. The floor weighs thirty tons, and its transformation from a horizontal to an inclined position is effected with great rapidity by means of hydraulic machinery.

IN commemoration of Jenner's discovery of the benefits of vaccination, a special meeting of the Russian National Health Society was held at St. Petersburg a few days ago, a large and distinguished company being present. A report of the meeting, and a description of the exhibition held in connection with it, appears in the current number of the *British Medical Journal*. The opening speech was made by the Grand Duke Paul, the Honorary President of the Society; and addresses in praise of Jenner and his work were delivered by Dr. Kudrin, the acting President; Prof. Lukianoff, the Director of the Imperial (Oldenburg) Institute of Experimental Medicine; and Dr. Kormillo. The results were announced of the competition for the prizes, which, it will be remembered, the Russian National Health Society offered for the best work on vaccination. Thirty-two essays were received, in various languages. The Society's gold medal and 1000 roubles, which had been originally offered, was not awarded. A gold medal was given to Dr. Layer, of Bordeaux, for his essay in French, "À la mémoire d'Edouard Jenner"; a gold medal to Dr. Miller, the Chief Physician to the Moscow Foundling Hospital; a small gold medal to Dr. Glagolef; and silver medals to Dr. Delobel, and M. Kazet, veterinary surgeon.

A SPECIAL telegram to the *Daily Chronicle* announces that Mr. Fitzgerald and Zurbriggen, the Swiss guide, began to climb Mount Aconcagua, in the Andes, on Christmas Day. At a height of 21,000 feet, Gussfeldt's card, dated March 1883, was found in a tin box. The explorers had to descend to the valley for three days, but a second attempt was begun on December 30, and an altitude of 22,500 feet was reached on January 2. A third attempt to get to the top of Aconcagua was commenced a week later. The *arête* between the peaks, at a height of 23,000 feet, was reached on January 14. Mr. Fitzgerald then had to turn back, but Zurbriggen reached the summit, which is over 24,000 feet high. This is the greatest altitude yet attained by mountaineers. The following item of climbing history is abridged from an article in the *Chronicle*:—"The serious business began with De Saussure, and has been going on ever since. He wa

soon followed by Humboldt, who climbed Chimborazo (19,000 feet) in 1802. The next climber to set foot on that mountain was Mr. Whymper, in the year 1880. The Jungfrau was first ascended in 1811, and the Finsteraarhorn in 1812. The other Swiss peaks have fallen one after the other—the Wetterhorn in 1854, Monte Rosa in 1855, and the Matterhorn in 1865. Mr. Freshfield scored the first great victory when he climbed Elbruz (18,526 feet) in 1868; but long before that Gerard had climbed to 19,410 feet on Porgyul in 1818. The highest climbs of later years have been those of Sir Martin Conway, who climbed Pioneer Peak in the Himalayas in 1892, and of Mr. Mummery and Mr. Hastings, who climbed to 21,000 feet on Nanga-Parbat. Dr. Gregory reached to about 16,000 feet on Mount Kenya in Central Africa (20,000 feet high), and Hans Meyer reached to 16,830 feet on Kilima N'jaro. In Asia there are four colossal mountains which still defy all efforts. Mount Everest (29,000 feet) still lies far beyond the reach of man. Dapsang (28,700) is almost equally inaccessible. Tagarma (25,800) and Khan-Tengri (24,000) have yet to be scaled. Similarly, in Africa, the highest mountain is still a virgin; and though Mount Cook (12,349) has been climbed in New Zealand, Charles Louis (20,000) still remains unascended in New Guinea, and seems likely to remain so."

A TOUCH of real winter has been experienced over the British Islands during the last week, and the thermometer has in many places registered a lower reading than on any previous occasion since winter set in. Towards the close of last week, and especially on Friday and Saturday, snow fell very generally at many of the English stations, and on Saturday night there was a fairly heavy fall in the metropolis. The snow quickly disappeared from the more crowded parts of London, but it remained unthawed in the suburbs on Tuesday morning. The thermometer in the screen at night has registered 10° or 12° of frost in many parts of Great Britain, while the exposed thermometer, on the grass, has fallen several degrees lower. The type of weather over our Islands has become anticyclonic; and if these conditions continue, a spell of settled cold weather will be experienced.

THE two young naturalists of the University of Cambridge (Mr. J. Graham Kerr and Mr. J. S. Budgett), who left England in August last for the Chaco Boreal of Paraguay, in quest of specimens of the American Lung-fish (*Lepidosiren paradoxa*), appear to have been very successful. Letters recently received from Mr. Kerr inform us that on arriving on the Upper Paraguay they found that there had been a mission station lately established in the Chaco, near the very spot where *Lepidosiren* was said to be most abundant. On arriving there the travellers were entertained on roast *Lepidosiren* for supper the very first evening, and found that this queer fish was very common in the surrounding swamps. A large series of specimens and eggs in every stage of development has been obtained, and Messrs. Kerr and Budgett will shortly return home with their collection in order to work out the results, which promise to be of no little interest.

A REUTER correspondent at St. Petersburg reports the arrival there of two Danish officers, MM. Oloufsen and Philipsen, on their return from a journey of exploration to the Pamir country, where they reached places hitherto untrodden by Europeans. They have brought back with them over 300 photographs of places they have visited and types they have met. During their travels they met, among others, tribes who are still fire-worshippers and totally uncivilised in their mode of life. It is said that the men of these tribes and even their animals are of very small size, the bulls and cows being no larger than a European foal, the donkeys about the size of a large dog, and the sheep about as large as a small poodle. The use of money is unknown to them, and their only trade consists in the bartering of furs. Women are bought at the rate of five or six cows or fifteen sheep apiece. These natives are very timid, and on the approach of strangers take to flight. MM. Philipsen and Oloufsen have secured numerous scientific collections, which they intend presenting to the Natural History Museum in Copenhagen, and have also made interesting meteorological observations. In the course of their voyage they occasionally reached a height of 14,000 feet above the level of the sea.

THE annual meeting of the Institution of Electrical Engineers was held on Thursday last, and Sir Henry Mance, C.I.E., succeeded Dr. Hopkinson as President. The Institution has been in existence twenty-five years, and it now has three thousand members. Founded originally by electricians and telegraph men, it has adapted itself to modern requirements, with the result that it is now the oldest and largest society of electrical engineers in the world. In the course of his presidential address, Sir Henry Mance, who has been actively connected with submarine telegraphy for the best part of his life, said that the earliest record of a subaqueous line is that of the experiment made by Baron Schilling, who, in 1812, exploded mines across the river Neva, using wire insulated with india-rubber. The earliest record at Somerset House of any submarine telegraph company is dated June 16, 1846, when the late Jacob Brett and Alexander Prince obtained a renewal of their provisional certificate of registration for the General Submarine and Oceanic Telegraph Company. The first concession connected with international submarine telegraphy was also granted to Jacob Brett in 1847, so that this year we may fairly be said to have reached the jubilee of the inception of international telegraphy. Sir Henry Mance said he had come to the conclusion that to no one individual could fairly be granted the credit of the inception and development of the submarine cable; the work was the work of many.

A DETERMINATION of the velocity of a flight of ducks, obtained by triangulation, was made at the Blue Hill Meteorological Observatory on December 8, and is described in *Science* by Mr. Helm Clayton. While engaged with Mr. S. P. Fergusson in measuring clouds, a number of ducks passed across the base-line, which is 2590·3 metres (8496 feet) in length. The observers succeeded in obtaining a simultaneous set of measurements on the apex of the flock, and one or two independent subsequent observations, and from these data the height of flights, as well as the velocity, was calculated. The height was 958 feet above the lower station, which is situated in the valley of the Neponset River, above which the ducks were flying. The velocity of flight calculated from this measurement of height, and from the angular velocity measured at the ends of the base-line is 47·8 miles an hour. The wind was very light, having a velocity of only two miles an hour according to the automatic record made at Blue Hill Observatory, 615 feet above the valley station. The direction of the wind was from the north, and the ducks were flying from the north-east.

A PAPER on "The Monier System of Construction" was read by Mr. Walter Beer, at the Institution of Civil Engineers, on January 15. The system originated in the attempts of a Parisian florist, named Monier, to obtain large vessels of a material more durable than wood and lighter than concrete. The principle of the system is the combination of Portland-cement concrete with iron or steel in such a manner as to develop in the same material the high resistance, to compression and binding of the former, and the great tensile strength of the latter. It has been found that in such a combination the good qualities of both materials are retained, and no chemical action occurs between the iron and the moisture in the concrete. The latter adheres firmly to the

smooth surface of the metal; and the coefficients of expansion of the two constituents are for all practical purposes identical. The economy of the system in the construction of girders and arches is considerable, owing to the great strength and compactness obtained, and, further, the material is absolutely fire-proof. Large spans may be used for floors, and the small amount of head-room required is a factor often of great value. The system can also be used in situations where brick and stone would be impossible.

IT is well known that air-currents containing either drops of water or fine dust in suspension give rise to electrification whenever they impinge on a solid obstacle. M. P. de Heen, guided by the view that electricity, independently of all luminous phenomena, can produce photographic impressions, has tried the experiment of allowing a current of air, laden with *Lycopodium* powder, to fall on a sensitive plate, and the photograph thus obtained is reproduced in the *Bulletin* of the Belgian Academy. With an uncovered plate, a feeble but distinct impression was obtained after one and a half hours, but by using a covered plate a much more powerful impression was produced. The most remarkable feature is that where the covering has been broken away dark ramifications are seen extending some distance into the covered portion, and these appear to follow the directions in which electricity has been propagated along the surface of the plate. In this connection attention may well be directed to the experiments described on p. 269 of this number of NATURE.

THE relative transparency of the alkaline metals to Röntgen rays, forms the subject of a note by Prof. C. Marangoni in the December number of the *Atti dei Lincei*. The author draws the following conclusions: (1) The most transparent metal is lithium, and its transparency does not increase with the thickness; (2) the anomaly of the greater transparency of sodium relative to potassium would suggest that the transparency for these rays is a function of the atomic weight as well as of the density.

IT is satisfactory to note that local fishery authorities are becoming increasingly interested in the scientific study of sea fisheries. The Northumberland Sea Fisheries Committee carried out in the summer of 1896 a series of trawling excursions in the bays of its district for the purpose of examining their condition and their productiveness, and a report on the results, drawn up by Mr. Alex. Meek, has been published. Mr. Meek is attached to the Durham College of Science at Newcastle-on-Tyne, and the more deliberate studies of the material collected were carried on in that institution. The report contains interesting details concerning the animals captured in trawl and tow-net, the pelagic eggs, and the food of the fishes.

THE latest instalment of the "Account of the Crustacea of Norway with short descriptions and figures of all the species," which Prof. G. O. Sars is publishing, forms the commencement of vol. ii., and of the description of the Isopoda. The general remarks on the Order only occupy three pages. The classification employed is that adopted by the author in 1882, the Order being divided into six tribes according to the characters of the first pair of legs, of the last pair of appendages (uropoda), and of the five pairs in front of the last (pleopoda). The first tribe, Chelifera, is distinguished by the fact that in its members the legs of the first pair are cheliform, that is, have prehensile claws. Twenty-six species in this tribe are described, and these are figured on sixteen autograph plates.

IN the last number of the *Records* of the Geological Survey of India, there is recorded a discovery by Dr. J. W. Evans, which adds another to the long list of geological resemblances between the peninsula and South Africa, and is also of some economic importance. This is the sedimentary nature of the gold-bearing rocks of Mysore, Dr. Evans having proved that what had been regarded as a quartz vein is in reality a quartzite.

THE following are among the lectures to be delivered at the Royal Victoria Hall, Waterloo Road, during February:—February 2, Mr. H. Bernard, on "Scorpions and their Relations"; February 9, Mr. R. A. Gregory, on "Photography of the Heavens"; February 23, Dr. J. W. Waghorn, "X and other Rays of Light."

THE fiftieth annual general meeting of the Institution of Mechanical Engineers will be held on Thursday and Friday, February 4 and 5. On each occasion the chair will be taken by the President, Mr. E. Windsor Richards. The following papers will be read and discussed, as far as time permits: "Fourth Report to the Alloys Research Committee," by Prof. W. C. Roberts-Austen, C.B., F.R.S. (Thursday); "Partially Immersed Screw-Propellers for Canal Boats; and the influence of Section of Waterway," by Mr. Henry Barcroft (Friday); "Mechanical Propulsion on Canals," by Mr. Leslie S. Robinson, of London (Friday).

THE first number for the current year of the *Biologisches Centralblatt* contains the commencement of an important article, by Dr. T. Bokorny, on the organic nutrition of green plants, and its importance in nature.

NUMBER 1 of vol. xxxii. of the *Proceedings* of the American Academy of Arts and Sciences is devoted to contributions from the Gray Herbarium of Harvard University, of interest to students of the flora of the United States.

PART XVII. of Dr. R. Braithwaite's "British Moss-Flora" has just been received. It commences Section 8 of this very valuable work, and deals with the Hypnaceæ. The two remaining families of Pleurocarpous mosses will be described in future parts.

We have received the Part for December 1896 of the *Agricultural Students' Gazette*, edited by students at the Royal Agricultural College, Cirencester. It contains papers on coffee-planting in British Central Africa; on clearing and preparing forest-land for cane in Queensland; and on experiments on permanent grass on the Lydney Park Estate, Gloucestershire.

MR. STEPHEN MARRIOTT has sent us a little book of his, entitled "To Winnipeg, Manitoba, and Back" (Simpkin, Marshall, and Co.). Though primarily of interest to intending emigrants, it contains much information worth reading; and, in view of the visit of the British Association to Canada this year, should find readers in the scientific world.

THE additions to the Zoological Society's Gardens during the past week include two Patas Monkeys (*Cercopithecus patas*, ♂ ♀) from West Africa, presented by Mr. W. Loy; a Prairie Marmot (*Cynomys ludovicianus*) from North America, presented by Mr. W. Hewlett; two Kestrels (*Tinnunculus alaudarius*), British, presented by Miss Fanny D'Aeth; a Greater Black-backed Gull (*Larus marinus*), British, presented by Mr. W. Theobald; a Pardine Lizard (*Acanthodactylus pardus*), a Scutellated Lizard (*Acanthodactylus scutellatus*) from Biskra, Algeria, presented by Mr. H. B. Hewetson; two Indian Pythons (*Python molurus*) from India, three West African Pythons (*Python sebæ*), deposited.

OUR ASTRONOMICAL COLUMN.

COMET PERRINE 1896, DECEMBER 8.—In this column for December 31, 1896, we referred to the striking similarity between the elements of the comet discovered by Mr. Perrine on December 8, and those of the Biela comet. Dr. F. Ristenpart finds, however (*Astr. Nachr.*, No. 3396), that the resem-

blance between these two comets is greater than was at first supposed, the origin of the unsatisfactory large differences for the mean places having been found out. The elliptic elements, which he has now calculated, give us less reason, then, to doubt the probability of a connection between these two comets. Dr. Ristenpart compares his elements with those of comet Biela at the time of its appearance in 1852, but suggests that more observations must be used in the investigation before an accurate value of the eccentricity, and therefore of the period, can be obtained. The comparison is as follows :—

	Comet Perrine 1896.	Comet Biela 1852.
	τ Nov. 24·7433 B.M.T.	
ω	163 57 30 5	223 17

DOUBLE STAR MEASURES.—Mr. R. G. Aitken communicates to the *Astr. Nachr.*, No. 3395-6, his measurements of double stars during 1895-6 with the 12-inch and 36-inch equatorial telescopes of the Lick Observatory. The majority of the measures were made with the former instrument, but occasionally the 36-inch was used for any crucial test. The selection of objects was restricted; no special search was made for new doubles, and great care was taken to determine the proper quadrant when two stars of nearly equal magnitude were being observed. In the micrometric measurements published, Mr. Aitken gives double weight for observations made with the 36-inch; the position angle is the mean of four or more settings, and the distance that of three double-distances.

The following are some of his remarks on interesting doubles and questionable doubles :—

OΣ 65 (Mag. 6·5, 7·0).—Certainly a physical pair, and the plane of the orbit appears to be in the line of sight. Further measures are needed at short intervals.

H VI 101 δ Tauri (Mag. 4·0, 9·0).—Distance appears to be slowly increasing.

Σ 634 (Mag. 5·0, 8+).—Rectilinear motion. Stars are moving in nearly opposite directions. Distance in 1834 was 34″, in 1896, 14·75.

H 1222.—Examined this star with the 36-inch powers to 1000. Star apparently single (1896·475). Conditions good. "Strongly suspected close double" by H. Looked for by β in 1876 without success. Probably a mistake on the part of H.

OΣ 269 (Mag. 6·5, 7·0).—Companion of this rapid binary has completed more than one revolution since the measures of OΣ. From measures down to 1891, β finds a period of 48·4 years.

Σ 2026 (Mag. 8·9, 9·0).—Undoubted binary. Angular motion should now become more rapid.

OΣ 342. 72 Ophiuchi.—With 36-inch powers 1600. Apparently single (1896·488). Powers to 2600. "No certainty of elongation" (1896·513).

Measured as a close pair by OΣ and others, but β has always found it single in the last twenty years. Probably the companion is an illusion.

β 989 x Pegasi (Mag. 5·0, 5+).—Shortest period of any known binary 11·37 years.

THE CANALS OF MARS.—We have received a communication from Herr M. Teoperberg, of the Hague, in which he submits an explanation of the formation and doubling of the canals on Mars. The idea which he suggests is one that will scarcely recommend itself to astronomers, for, indeed, *one* assumption cannot reasonably be admitted. The writer supposes a periodical downfall of snow to be the principal agent, taking the undoubted bands as the crests of anticlinals, the bases of which may be veiled from the observer by increase of absorption. Such a range, he says, presenting itself as a narrow band, will be doubled if the higher part of the crest be covered with snow. With the advance of the season the snow-covering will extend downwards on the slopes of the ridge, and its margin will at last dip into those strata which escape our observation: the bands will then be lost for a time, reappearing by the inverse process at the next change of season. As another instance of such combinations, he says, "a synclinal, filled up in winter with snow extending also, but in thinner layers, over the bordering ranges, will present a double band as soon as these more exposed ranges are laid bare by the melting of the snow in summer. They will then change into a single band when the central thicker mass of snow has melted away and replaced either by the dry valley ground or by a drowned *Thalweg*, these recalling the canals *prop. dict.*, differing, however, therefrom by a probably high situation and by the elevated ranges on the sides." Sufficient, however, has been quoted to show that the writer must assume in his hypothesis innumerable ranges of mountains, the highest peaks of which must be singularly placed to give the effect of straight lines or arcs. It is true that horizontal sections of mountains become more simplified the greater the elevation, and that gaps of considerable magnitude would escape observation, but even then the mountainous conditions on Mars would be very extraordinary. If such were the case, the "flashings" would be very much more numerous than they are, and the colour phenomena would probably be different from what observations tell us. The hypothesis of "vegetation" seems still to be the most satisfactory explanation for these curious canal-like markings, although even this cannot satisfy all the observed phenomena.

THE CLASSIFICATION OF MADREPORARIA.

AT present the classification of Madreporarian corals is admitted to be in an unsatisfactory condition. A fair standard of the opinion of the time can be obtained by reference to Prof. Nicholson's "Manual of Palæontology," or to Prof. von Zittel's new "Student's Text-book of Palæontology." One of the most striking features is the insecurity which is now felt about the sub-orders of Milne Edwards and Haime, the M. Rugosa = Tetracoralla (Haeckel), and the M. Aporosa and Perforata = Hexacoralla (Haeckel). Yet the authorities just named think it best to maintain these sub-orders provisionally.

I propose here to give a short sketch of some work of mine on corals, which was entered at the Royal Society of London in July 1895. It deals with the "Microscopic and Systematic Study of Madreporaria," and covers a rather wide field :—

(1) Numerous sections of the skeleton of living corals are examined and figured, all controversial points with regard to the structure of skeletal parts are exhaustively discussed, and my own views are advanced regarding microscopic structure, and the relation of the soft parts of the polyp to the skeleton.

(2) A comparative account is given of the fossil skeleton in the various families. In this part I have been greatly aided by the results of my special work on corals of Upper Jurassic age, "Stramberger Korallen," to be published next month in the *Palæontologische Mittheilungen* (Stuttgart).

(3) The determination of the main evolutionary changes within Madreporaria.

(4) Systematic results.

General Microscopy of the Skeleton.

The basal "tabula" or "dissepiment" forming the floor of the calyx presents us with the simplest form of septal structure in Madreporarian corals. Microscopically examined, it proves to be a compact series of calcareous lamellæ, each of which is made up of minute, crystalline, needle-shaped fibres, set perpendicularly to the lamellar surface. The fibro-crystals are oriented in one and the same direction throughout the whole thickness of lamellæ, hence they behave in the same way towards light. The appearance under the microscope is that of long fibres running through the lamellæ, but crossed by a dark and light band in each lamella (Fig. 1). These bands are wavy, not straight in section, and a special group of tiny fibres is present within each "wave." *The solid dimensions of such a fibrous wave-unit or "scale"* (Fig. 2) *of the lamella agrees with those of a single ectodermal cell of the polyp.* The wave-units of the lamellar surface indicate the original cell units, whose protoplasmic contents have been changed to crystalline fibres. Still, however, some fragments of organic matter and dirt particles usually remain, and their decomposition gives rise to the dark spots and bands which blur the crystalline deposit.

The structure just described for the calcareous floor of the coral calyx repeats itself throughout all parts of the skeletal

tissues. It is the structure characteristic of the Madreporarian skeleton. The endless variety of form, which we find among the skeletal parts, is produced by corresponding varieties in the calicoblastic layers of the polyp. With this difference, that the

FIG. 1.—*Galaxea dissepiment*: *g.l.*, growth-lamellæ.

calcareous lamella is, as it were, the "cast" of the ectodermal flesh.

The cell-for-cell equivalence of the skeleton with the outer polypal layers explains why the fine microscopy of fossil and

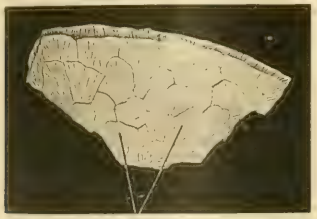

FIG. 2.—Calcareous scales on the surface of a dissepiment (from the cœnenchyme of Galaxea) highly magnified.

recent skeletons may guide the systematist in tracing the affinities between Madreporarian genera and families. I shall next consider the outstanding varieties of form which I recognise in the septa of typical Madreporaria.

Septal Forms.

Bearing in mind the origin of the radial or septal fold as an invagination of the embryonic "basal plate" of the polyp, it will readily be understood that there are two opposite calicoblastic surfaces in the radial invagination instead of one surface, as in the tabula or dissepiment. Fibrous lamellæ are formed along the entire external surface of the fold. If the invagination is conical, or nearly so, naturally so is the skeletal deposit which it lays down; if smooth, the deposit is smooth. Such is the deposit of the "*septal spine*," which we see projecting inwards from the wall in many Palæozoic corals, and may still find in several species of Madrepora and other living corals The lamellæ are formed in the septal spine around a central axis, and as the fibro-crystals are oriented rectangularly in the lamellæ, they radiate out from this axis.

Considerable notice has been taken in current literature of the central part of the spine and of its analogue in the flat septum, called the "dark line" or "primary septum." I find that the opacity of the "dark line" or "axis" is due to the same cause as the "dark bands," or closely-strewn "dark points," which occur in the fibro-crystalline deposit in the tabula, dissepiment, or any skeletal part. The organic cell remnants are, however, massed together in the axial portion of a conical or oblong fold, and the "dark points" therefore appear more prominently in sections of septal spines and septa than in sections of a one-sided structure like the dissepiment. There is a further observation. Several of the first few layers laid down by the adjacent surfaces of a septal fold are in many cases less completely calcified than the next in age. Apparently skeletal deposit accumulates more rapidly at the septal edges than lower down on the septal sides, but the crystalline changes in the cell are less complete. While I regard the presence of disintegrating carbon products as the original cause of the "dark line," it is well known that the "line" may ultimately assume various appearances due to secondary changes (see Hinde, "On Septastræa," *Q. J. G. S.*, 1888), or may be represented by a hollow space.

If the septal invagination is long instead of round in shape, it stretches through a certain radial length in the calyx, and the calcareous deposit takes the form of a *flattish septal plate* in consequence. The lamellæ are symmetrical on either side of the "dark line," which indicates the axis or median plane of the fold. We are familiar with microscopic transverse sections of flat, plano-symmetric septa in Palæozoic Zaphrentids, as well as in our own Turbinolids. The septal spine and the plano-symmetric septum are the two most primitive forms of septal deposit, and sometimes the flat septum passes at its inner edge into spinate prolongations.

We now come to more elaborate forms. The *striated septum* (Fig. 3) develops within the flaps of a septal fold, which, in-

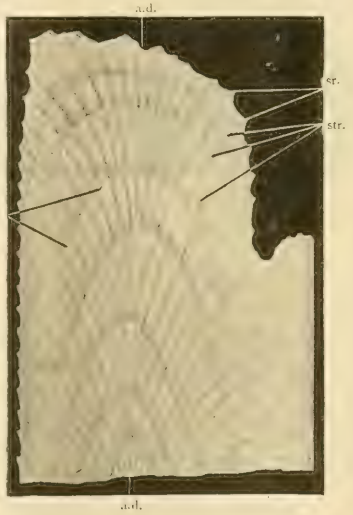

FIG. 3.—Striated septum of Galaxea. The striæ diverge fan-like from an "area of divergence" (*a.d.*): g.c. = growth-curve.

stead of being smooth, is thrown into a regular system of pleats, and has a goffered edge. The surfaces of the calcareous lamellæ are consequently marked by striæ (str.) and grooves, and the striæ taper to fine serræ (sr.) at the edge of the septum. In microscopic transverse sections of striated septa, the fibro-crystals radiate out from "dark points," better called "centres of calcification," which form a row in the median plane (Fig. 4). Each "centre" represents in cross-section the long axis of a stria, or pair of striæ, according as the striæ are alternate or opposite on the two surfaces of the septum. A number of wave-units of the lamellæ are arranged around each axis, hence the unit-bunches of fibres, though minute in themselves, combine to form a relatively large, radiating bunch to which I have given the name of "*fascicle*." It passes obliquely upwards and outwards through the series of lamellæ and gives rise to a slight eminence or "granulation" where it emerges at the surface. Striated septa occur in Stylinidæ, Oculinidæ, some Turbinolidæ, &c.; they are composed entirely of fascicles bisymmetrically arranged on either side of median axes.

It is a further step in complication of structure to pass from the striated septum to the roughly-granulate, ridged, spiniform-toothed septum which one sees in many Astræids, *e.g.* Mussa. Each broad ridge that passes downwards from a single spiniform

tooth of the edge bears on it a number of striæ, sometimes veiled superficially by the granulations, but always apparent after polishing the surface. This simply means that the septal fold in Mussa is thrown into a few very wide, deep pleats, corresponding with the broad ridges of the septal surface, and then that each wide pleat falls into a system of smaller, pitted pleats. Transverse and longitudinal sections show a departure from the

FIG. 4.—Transverse section of part of septum and wall, showing the radiating lines of structure passing out from the "dark points," and also the wavy cross-lines corresponding to successive "growth-lamellæ" (high power); gran. = granulation.

strict bisymmetry of fibres and uniform distribution of axes observed in the striated septum.

The septum of Heliastræa presents a further variation of the Mussa scheme. In microscopic transverse sections (Fig. 5), the fascicles are especially closely grouped in the middle, bulging part of a ridge, and are there arranged almost circularly; while, at the narrower ends of the ridge, the fascicles are further apart and are set bisymmetrically.

Next, in some Astræid types, and conspicuously in the family of Fungidæ, similar large ridges are present, but they are elliptical, squarish, or roundish in shape, indicating a still closer bundling together of the fascicles. As a fact, the fascicles radiate out around a common ridge-axis, although the individuality of the fascicles is still maintained. This is proved

FIG. 5.—Thick central portion of a septal ridge of Heliastræa formed by a radio-symmetric trabecula (*Tr.*); and the thinner lateral wings of the same ridge passing into corresponding furrows—only bi-symmetric trabeculæ (*tr.*) are present in these (magnified 70 times).

by the distinctness of emergent ends of fascicles in the thinner septa, and also by the inherent structure of parallel-set striæ. In thick septa, however, the emergent ends of fascicles coalesce to form the characteristic large granulations. These are the granulations, composite in structure, which give rise to "pseudo-synapticulæ" (Pratz), inasmuch as their large size enables those at the same horizon on adjacent septal surfaces to coalesce across the interseptal loculus.

Thus I have passed from a bisymmetric to a radio-symmetric arrangement of fascicles in septa. Throughout all these septal types, certain definite laws of growth can be observed. Each row of fascicles (Fig. 6) added along the growing septal edge, indicates a single period of growth in the existence of the polyp. I have, therefore, applied the term of "*growth-segment*" to signify one such addition made to the height of the septum; the term "trabecular part" to a pair or group of fascicles; and I define the term "trabecula" as a series of "trabecular parts" laid down during successive growth-periods of the polyp.

In the case of most Turbinolids the *basal* deposit laid down during a growth-period is in the form of a few more lamellæ added, without any spacial interruption, to the lamellæ of the previous growth-period. In the case of tall Astræids, Stylinids, &c., the basal deposit of each growth-period forms a new calycinal floor. And *the space between any one calycinal floor and its predecessor corresponds to one growth-segment of the septum.* This is a most important relation, and is one which I find also holds good for the synapticulate form of base. The "true synapticula" in Fungia and its allies would thus be homologous with a basal dissepiment, and is probably an acquired feature in them, modified from a more primitive dissepimental base. Certainly one finds that dissepiments dwindle or even disappear in these synapticulate types. The question arises of the possible advantage to the polyp of the synapticular in place of the dissepimental floor. The advantage is, at least, two-fold: (1) mechanical, as a support equally strong, although proportionally lighter; (2) physiological, as a means of extending the internal cœlenteric space by the canalicular elongations, which are supported between synapticulæ.

The septum of the Eupsammidæ is, as in the Fungidæ, frequently porous, and the interseptal loculi are bridged by the coalescence of septal ends, by pseudosynapticulæ, or by true synapticulæ. The pores of the Eupsammid septum, however, may occur not only between the adjacent "trabecular parts"

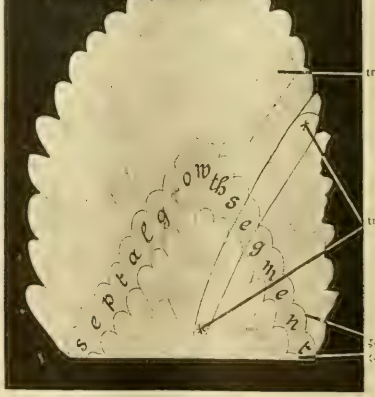

FIG. 6.—Radial structure composed of a "septal" wing and a "costal" wing. The trabeculæ diverge right and left from an "*area of divergence*" between the two wings. The single trabecula marked "*tr.*" is composed of seven trabecular parts (*tr.p.*) representing seven successive growth-periods. The trabecular parts between any two growth-curves (*g.c.*) form a "septal growth-segment," and represent one growth-period (diagrammatic).

of a growth-segment, but also between the successive "trabecular parts" in any one trabecula. Hence it is possible for a "trabecular part" to be absolutely free from its neighbours n

the same radial line—to be, in short, a *free septal spine set in the calyx*, as in the case of Palæozoic Cystiphyllids. The Triassic genera Stylophyllum and Stylophyllopsis show this same feature, also several Jurassic genera, *e.g.* Epistreptophyllum and Dermosmilia, and there is no doubt that we have here an important structural feature in a living coral family which can be traced back to a feature characteristic of certain Palæozoic genera.

The Eupsammids were associated by Edwards and Haime with the Madreporidæ (sub-ord. M. Perforata). But the septal structure is very different. My sections prove that Turbinaria and Madrepora possess *compact septa* of a strictly bisymmetric type like those of Turbinolids, Oculinids, Stylinids. Porites again, the type of the other "Perforate" family of Edwards and Haime, has a porous septum composed of radio-symmetric trabeculæ. The crystalline structure of the trabeculæ in the Poritidæ distinguishes them essentially from the Fungidæ. The homology of the so-called synapticula is also in my estimation different in Porites. I regard it as having the character of an *inter*trabecular, *inter*septal spine. It does not replace dissepimental deposit, and appears to be an *inherited feature*, not an acquired modification.

Reasoning now upon the foundation of the micro-structure of septa, I would draw the following conclusions respecting the classificatory system of Madreporaria.

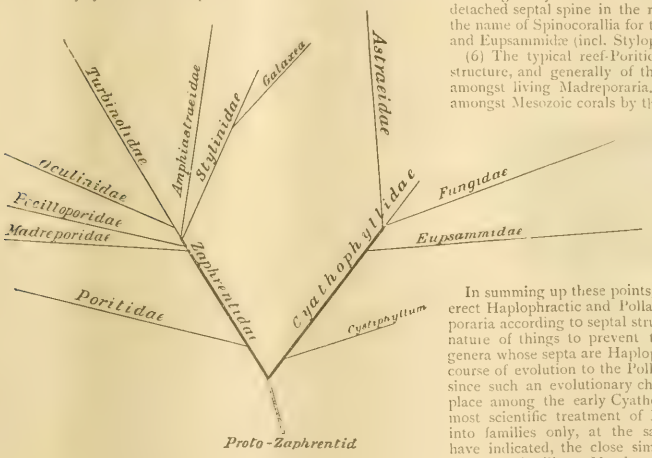

FIG. 7.—Phylogenetic diagram of Madreporaria.

(1) Septal structure affords a strong reason in favour of the abolition of the sub-orders Tetracoralla and Hexacoralla, since all the known septal types amongst Tetracoralla are also prevalent in Hexacoralla.

(2) Septal structure also disannuls the groups of M. Aporosa and M. Perforata. Madrepora and Turbinaria, typical genera of the group of M. Perforata, possess compact septa, whose structure is the same as the septa of certain typical genera belonging to the M. Aporosa. Again, similarity of septal structure characterises compact-septate and poro-septate types of Fungidæ; while one and the same specimen may have some of its septa compact, others porous.

(3) The two sub-families, Astræinæ and Eusmilinæ, hitherto recognised in the family of Astræidæ, have quite different types of septal structure. I would remove the genera of the Eusmilinæ to various other families, *e.g.* Euphyllia and allied genera to the Turbinolidæ; Amphiastræa and allied genera to a new family of Amphiastræidæ; Stylina, Galaxea, &c., to a family Stylinidæ.

(4) The fundamental similarity in the septal type of the families, Madreporidæ (excl. Eupsammineæ, E. H.), Pocilloporidæ (among which I would include Stylophora and its allies), Oculinidæ, Stylinidæ, Amphiastræidæ, Turbinolidæ, and the Zaphrentidæ among Palæozoic corals indicates a probable common ancestral line. The septal type is very simple, and shows bisymmetry of design. I give it the name of *Haplophractic*. Other considerations concerning the relations of septum and wall, and the general habit of growth, indicate a closer affinity of the colony-building families, Madreporidæ, Pocilloporidæ, Oculinidæ, Stylinidæ; they form a natural group which I call *Cœnenchymata*. While the remaining three families with the Haplophrastic septal type are characterised by a strong wall, retaining in part or wholly its primitive character as the inner lining of the epitheca. They may be termed *Murocoralliа*.

(5) The fundamental similarity in the septal type of the Astræidæ, Fungidæ, and the typical Cyathophyllidæ, the Eupsammidæ, and Cystiphyllidæ, indicates an ancestral relationship of these families with one another. Their septal type is characterised by complications due to the many pleatings of the septal invagination. I call it *Polaplophractic*, in contradistinction to *Haplophractic*, and it will be remembered that the radio-symmetric trabecula attains here its full perfection, and that the septa are frequently porous. The families Cyathophyllidæ, Astræidæ (excl. Eusmilinæ), Fungidæ, are characterised by the pre-eminence of the *septum* and septo-costa in the calyx, and the regularity in the trabecular structure. They may be allied, therefore, under the name of Septocorallia. On the other hand, the irregularity of the trabeculæ, and the occurrence of the detached septal spine in the radial structure, make me choose the name of Spinocoralliа for the allied families of Cystiphyllidæ and Eupsammidæ (incl. Stylophyllinæ).

(6) The typical reef-Poritids hold, by reason of their septal structure, and generally of their skeleton, an isolated position amongst living Madreporaria. A similar position is occupied amongst Mesozoic corals by the Tria-sic family of Spongiomorphidæ. It seems likely that these two are ancestrally related; but I have not been able to do more than suggest a possible Palæozoic ally in the Trheciidæ. Provisionally, I give the name of Porosa to the Poritids and Spongiomorphids, in reference to the porous network of trabecular parts which makes up the entire skeleton.

In summing up these points, I may say it is not my intention to erect Haplophractic and Pollaplophractic sub-orders of Madreporaria according to septal structure, since I know nothing in the nature of things to prevent the more advanced of the living genera whose septa are Haplophractic in type, to attain in the course of evolution to the Pollaplophractic type. All the more, since such an evolutionary change seems actually to have taken place among the early Cyathophyllids. In my estimation, the most scientific treatment of Madreporaria is to classify them into families only, at the same time bearing in mind, as I have indicated, the close similarities existing between certain groups of families. My plan of Madreporarian ancestry is represented in the accompanying diagram, and is more fully carried out in a phylogenetic "scheme" of genera given in the complete work (*Phil. Trans. R.S.*, vol. clxxxvii. (1896) p. 331).

I have purposely devoted the greater part of the space in this account to septal structure; other points can be merely indicated. The wall displays all the structural types just described for septa. The structure of the "wall" in fossil genera has an important bearing on questions concerning the "Randplatte." (I translate this term as "edge-zone.") It can be observed, for example, that in the early corals *the wall is the inner lining of the epitheca*, and the epitheca there extends up to the very lip of the calyx. The wall is therefore, like the tabula, primitively a one-sided structure. Both are laid down by continuous parts of the polypal ectoderm, and are skeletal forms homologous with the primitive inner lining of the embryonic basal skeletal plate. There cannot, therefore, have been any edge-zone of polypal flesh outside the calycinal wall of these early corals. Indication of an edge-zone is given when the wall in fossil genera is seen to rise up above the epithecal mantle at the edge of the calyx. It is then a two-sided structure developing within a fold, as in the case of septa. But the two flaps of the wall-fold may be quite different in length, as is testified by the varying position—central or excentric—taken by the "dark line" or fold-axis in the wall. This incoming of the edge-zone in corals took place at different times, and only in some genera; in others there has never been an edge-zone, so far as fossil evidence goes.

Speaking generally, I regard cœnenchyme as an elaboration or extension of mural and murocostate structures, formed above or within the epitheca.

I have above referred exclusively to the kind of wall which has been termed a "eutheca" (Fig. 8) or "true theca." Dr. Ortmann has defined it as a wall having distinct centres of calcification independent of these in the septa. In the case of

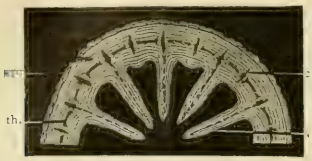

FIG. 8.—*Eutheca*. Transverse section showing the structural relations of *ps.*=septa, *c.*=costa, *th.*=theca, and *ep.*=epitheca, in a typical Turbinolid. The section is cut some little distance below the calycinal edge.

the primitive one-sided wall, I would remark that the layers are often so smooth, that no particularly marked ring of "centres" is seen next the epitheca.

The "pseudotheca" (Fig. 9) is defined as a "false wall" formed by lateral thickening of the septa, with or without the participation of basal structures. I find that "pseudothecal" thickening is a very general characteristic in the families with

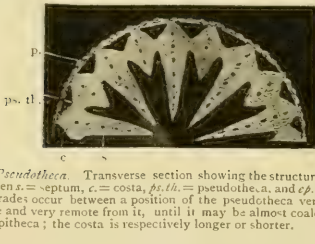

FIG. 9.—*Pseudotheca*. Transverse section showing the structural relations between *s.*=septum, *c.*=costa, *ps.th.*=pseudotheca, and *ep.*=epitheca. All grades occur between a position of the pseudotheca very near the centre and very remote from it, until it may be almost coalescent with the epitheca; the costa is respectively longer or shorter.

Pollaplophractic septa. Two walls, *i.e.* both pseudotheca and eutheca, were present temporarily or permanently in many fossil colonial genera belonging to Cyathophyllidæ, Stylinidæ, Amphiastræidæ, but, as a rule, the permanent presence of a pseudotheca is correlated with retrogression or absence of the primitive wall-lining of the epitheca, and even the epitheca itself, around individual calyces.

Evolution in the general Architecture of the Calyx.

The internal construction of the calyx has altered very considerably during the history of the Madreporaria. Originally, the Madreporarian calyx was shallow, with low septa ribbing the walls and base, and from one to four grooves (fossulæ) in the wall and base. Now, it has become typically deep-cupped, the septa are relatively higher and more ornate, centrally a columellar "style" rises upwards, or the septal ends meet irregularly in a columellar mesh-work, and instead of one to four special grooves, it is as if the whole base of the cup were grooved and deepened. These changes I take to be correlated, *and to have been initiated by an increase in the number of mesenteries bearing reproductive organs, and increase in the demand for space in which to accommodate and protect these organs in the calyx.* It is generally presumed that the primitive fossulæ were pits for the accommodation of a very few mesenteries specialised for reproduction. Whereas now all, or nearly all of the mesenteries in living corals can exert this function. The multiplication of reproductive organs in any species is, we may safely argue, an advantage to it in propagating its kind; certainly it is a change which has proved successful in all Madreporarian families adopting it. The Cyathophyllids were the most precocious of the Palæozoic corals in modifying their calyx; and I attribute to this fact the marvellous rapidity with which their descendants, the families of Astræidæ and Fungidæ, spread over early Mesozoic seas. To this day these families are probably the richest in genera and species.

The change in the architecture of the calyx was effected by a gradual modification of existing skeletal structures. The "tabula" degenerated or was changed to "columella"; it was only retained in its primitive form in the calyces of polyps which have never specially multiplied the number of their mesenteries, but have held their place owing to some other advantageous resource, *e.g.* cœnosarc. These are comparatively few.

The wall-lining of the epitheca was modified as I have indicated above. The septa were modified, giving rise to pseudothecæ inside the calyx, a valuable means for the support of mesenteries. In living families, the complicate Pollaplophractic type of septum goes hand in hand with much pleating and greater muscular vigour of the mesenteries. There can be little doubt that higher musculature and sensibility of mesenteries aids reproduction, hence these correlated features in septa and mesenteries were probably adaptations to this end. The synapticular base is another modification closely associated with the mesenteries, occurring as an occasional correlate in types with Pollaplophractic septa and a much-pleated aboral polypal surface.

In short, by comparison with well-known facts in the anatomy of living Madreporaria, it becomes clear that all the important changes which have taken place in the history of the group, are secondary features correlative with change in the mesenteries. There is also good evidence that the change in the mesenteries has assisted the polyp's powers of propagation. We need look no further for an explanation of the "hastening" in the stages of cyclical development of mesenteries or septa. The history of the embryo summarises that of the race; tetrameral symmetry is now for the most part an evanescent phase in embryonic development. On this point, any evidence I have gathered from Mesozoic corals only corroborates the published views of Prof. Quelch and Dr. Ortmann against a subdivision of Madreporaria into Tetracoralla (Rugosa) and Hexacoralla, and helps to still more emphatically knit continuity into the thread of Madreporarian descent from Palæozoic to recent time. Even now the change to radial symmetry of the polyp is often incomplete, and will be while there still are "directive" mesenteries.

In conclusion, I claim in this work to have shown that the great impulse of evolution—viz. the successful continuation of the race—is the agent to whose steady working the main changes in Madreporaria may be traced. I claim to have vindicated this position by demonstrating the same structural unit in the simplest and the most complicate skeletal structures known in Madreporaria through all ages, by finding in all skeletal parts one and the same fibrous equivalent of the living, lime-forming, unit cell, and by tracing a correlated series of modifications which primitive forms have undergone in response to the need of safeguarding the race.

MARIA M. OGILVIE.

THE POSITION AND WORK OF THE CENTRAL TECHNICAL COLLEGE.

THE Report of the Special Committee appointed by the Governors of the City and Guilds of London Institute, at the instance of the Court of Assistants of the Mercers' Company, to inquire into the expenditure of the Central Technical College as compared with results, has just been published. The Committee comprised not merely representative members of the City Companies, but present and past Presidents of the Royal Society, the Institution of Civil Engineers, the Chemical Society, and other societies interested in the advancement of knowledge, so that its opinion may be regarded as that of the scientific public. Sir John Donnelly was elected chairman of the Committee.

The volume runs into eighty pages, and deals with (1) building and equipment, (2) current expenses, (3) cost of the College per student and comparison with other colleges, (4) methods of administration and control over expenditure. We are glad to give it prominence, first, because the Central Technical College is not supported as a commercial concern to make money, but to provide, at small cost, a sound education in the applications of the principles of science to industry; and secondly, because the members of the teaching-staff are earnest and enthusiastic in their efforts to carry ont the scheme formulated some years ago, when the estimates of the cost of the College were drawn up by Huxley and others.

It would be a distinct impediment to the progress of the higher technical teaching, if the present scheme (which supplies education to students at one-third of the annual cost, or for about one sixth of the total cost if interest on capital expenditure be added) were interfered with, by the obstruction offered by those who would prefer that the City Companies' funds should be spent on food for the body rather than for the mind.

From the Report of the Sub-Committee on Finance and Administration the following particulars have been derived :—

The Central Technical College was completed in 1884, and cost £79,200. The original equipment cost £22,600; making a total of £101,800.

In the following table is given the original capital expenditure on the College as compared with the capital expenditure estimated by the Livery Companies' Committee of 1878, in consultation with the expert advisers, together with capital expenditure on other colleges in England and abroad—

Central Technical College		£101,800
Approximate cost as suggested by—		
Prof. Huxley	£100,000	
Sir Douglas Galton ...	150,000	
Sir John Donnelly ...	100,000

Since the original equipment of the Central College was furnished, a further sum of £9500 has been spent on apparatus, books and fittings of a permanent character, partly out of the general funds of the Institute, and partly out of special grants.

It is instructive to notice the cost to the College per student in comparison with other Colleges.

In England, Cooper's Hill Engineering College provides a training in engineering and forestry for about 100 students, more especially with reference to the requirements of the Indian Service; the College is under the India Office, and the gross cost per student amounts to about £170 a year; this, however, includes residence, the cost of which does not exceed £50 per student. The Royal College of Science, under the Science and Art Department, is attended by about 300 students, about half of whom are free scholars; the cost, exclusive of scholarships and exhibitions, is estimated for the current year at £20,364 (Civil Service Estimates), but this does not appear to include charges for rates, repairs, or library. The amount received for fees is about £3200, leaving the net cost at about £16,800. The gross and net cost per student is therefore about £67 and £57 respectively.

In the United States, America, the technical school which most nearly resembles the Central Technical College in its organisation is the Massachusetts Institute of Technology, at Boston, which, however, includes in its curriculum, in addition to the subjects of civil, mechanical and electrical engineering and chemistry, taught at the Central Technical College, several others which in England are provided for at the Royal College of Science, besides sanitary engineering, architecture, and shipbuilding. The courses of study cover a period of four years, and the total number of students is between 1100 and 1200. The institute has several buildings, each about the size of the Central Technical College. The expenditure in 1894 was £70,610—namely, salaries £41,900, laboratories and library £6760, and sundries £21,950. The income derived from the students' fees, £44,190. The gross and net cost per student was about £60 and £22 respectively. The gross annual cost per student at Cornell University, where science and engineering students greatly preponderate, is about £63; the number of students during the session 1894-5 was 1503, and the income derived from fees £30,000, or on an average £20 per student, making the net cost per student about £43. The income and expenditure of the Johns Hopkins University, Baltimore, was in 1893-4 £36,250, and the number of students in 1894-5, 589; the fees charged to students vary from £30 to £40. The gross and net cost per student would therefore be about £61 and £25 respectively.

At the McGill University, Montreal, the expenditure of the Faculty of Applied Science for the session 1895-6 amounted to £60 per student, and the net cost per student, after deducting receipts from fees, to £29.

The organisation of, and conditions of admission to, the technical high schools or polytechnics of Germany are so different from the Colleges just mentioned, that no accurate comparison can be drawn between them; but the following statement from the second Report of the Royal Commission on Technical Education, 1884, is of interest as showing what Germany was at that time doing for technical education :—

"It may be mentioned that in the polytechnics of Germany there is accommodation for about 6000 students, whilst the total attendance is little more than 2000, and the annual cost to the State of each student, exclusive of interest on capital, is about £100" (vol. i. p. 209). Since that Report of the Commissioners, the accommodation in Germany for technical students has greatly increased, and at Charlottenberg (Berlin) alone there are over 2000 students, including, however, occasional students. The fees at the technical high schools in Germany amount, for a full attendance, to about £12 a year.

Perhaps the most celebrated polytechnic on the continent is that at Zurich, Switzerland, which in its organisation closely resembles the Central Technical College, although several times as large, and embracing a much wider range of courses of study. Her Majesty's Secretary of Legation at Berne, in a recent report on education in Switzerland, states that—"In the Polytechnic School of Zurich, to which the Federal Government makes an annual grant of £36,800, there are 720 pupils, of which 309 are foreigners. Instruction is given in architecture, civil engineering, mechanics, chemistry, forestry, and training of teachers. The fees are about £8 10s. per pupil." Assuming that there is no other source of income, this would make the gross and net cost per student about £59 and £50 respectively.

The foregoing approximate results, excluding board and lodging, are shown in the following table :—

—	No. of students.	Gross cost per student.	Net cost to Institute per student.

The Sub-Committee on the educational work of the College report that three classes of students attend the courses. There are those who hope to qualify for the diploma and take the three years' course of instruction as laid down in the programme; those who attend one or more departments only with a view of completing or continuing their instruction in special directions; and those who attend short courses of lectures or laboratory work in some special branch of applied science.

The questions set at the entrance or matriculation examina-

tion of the Central Technical College during the last few years show that no institution in the kingdom requires from candidates for admission the same standard of attainments. Indeed, with the exception of two institutions, none of those receiving any part of the Government Grant of £15,000 a year allocated to University Colleges, require students above sixteen to submit to any entrance examination whatever, and the examination of these two is of the simplest character, and bears no comparison with that of the Central Technical College. The Committee considers, therefore, that the Central Technical College is somewhat handicapped in its competition for students by the difficulty of its matriculation examination. At the same time they are of opinion that it is important that an institution, avowedly intended for higher education, should require candidates for admission to pass such an entrance examination.

There is another class of students for whom provision was made in the original scheme, in attendance at the College, who are not required to pass the matriculation examination, nor to take any prescribed course of study. These are the so-called "special" students. They are in most cases students of more advanced age, who are desirous of pursuing for a session, or even a part of a session, a special line of study, with a view to qualifying for some particular industrial position or for teaching purposes, or for research work. Of such students, some have graduated at other universities, here or abroad; others have already been engaged in commercial works; and the evidence received from former students of this class satisfies the Committee as to the advantages derived from the facilities which the Central College offers for such specialised study. The gain to industry and commerce, and to the progress of science by the steady work and the careful researches of such students, is alone ample justification for the expenditure which the maintenance of an institution affording such facilities involves.

Although the number of students in attendance at the College cannot be considered, by itself, a sure criterion of its success, there is no other institution in Great Britain or Ireland in which so large a number of student are receiving advanced instruction of the same character as that given at the Central Technical College.

In considering the educational work of the College, the large number of contributions to the advancement of science which have been made by the Professors individually and in co-operation with their students are referred to. Indeed the spirit of research pervades every department of the College.

The teaching is well calculated to give to the student that general knowledge of scientific principles which all practical men regard as of primary importance, supplemented by the experience in the application of those principles to the methods of original investigation.

The knowledge which the students are enabled to acquire in the engineering workshops, of the construction and use of machine and other tools, is especially useful in subsequently helping them in their own experimental work, and in enabling them to profit more quickly by the experience of the factory or workshop.

As regards the salaries of the Professors, that there are four Professors who each receive a fixed stipend of £1000 a year without any share in the students' fees. At most other Colleges the practice is to give the Professor a smaller salary and a share in the fees. Both practices have advantages; but the Committee are disposed to give the preference to the system adopted by the City Guilds—of making the Professor quite independent of his students' fees, so that he may have no interest in admitting unqualified and insufficiently prepared students into the College. Indeed, with a difficult entrance examination, such as that of the Central College, the fact that the Professors' remuneration depends in no way upon the fees paid by the students removes any suspicion of a tendency to undue leniency on their part in the admission of the students. Several of the Professors in other institutions are more highly remunerated, and enjoy at the same time a larger measure of liberty than those at the Central Technical College. At Liverpool, the payment to the Professor of Physics for the year 1894-5 was £1177 16*s.* 7*d.*; to the Professor of Engineering £1039 17*s.* 7*d.* At University College, London, the payment to the Professor of Chemistry for the same year was £1100 13*s.* 4*d.* At Owens College, Manchester, the Professor of Mathematics received £1048 6*s.* 8*d.*; the Professor of Chemistry £1220 13*s.* 8*d.* At the Scotch Universities the salaries of the Science Professors are considerably higher.

The Educational Committee, finally, express their opinion that the work of the College has been eminently successful, and that the City Guilds Institute is to be congratulated on what it has accomplished. The results achieved are, in their opinion, fully commensurate with the expenditure involved.

Having regard to the higher appreciation of the advantages of advanced technical instruction, which a further knowledge of what is being done on the continent and in the United States is likely to bring about, it is believed that in the near future, the Central Technical College will be found too small for the number of students who, attracted by the excellence of the training it offers, will seek admission, and that the question of the extension of the building may before long have to be considered.

The Reports of the Sub-Committees on Finance and Administration, and on the Educational Work of the College, were adopted by the Committee. To sum up the case, this Committee reports that, in their opinion, the Governors of the City and Guilds of London Institute possess in the Central Technical College an Institution which has well and economically carried out the objects for which it was founded; and that those objects are well deserving of every support and encouragement that the Corporation and City Companies of London can give to them.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. James Ward, whose name is well known as a physiological psychologist, was on Saturday elected to the new Professorship of Mental Philosophy and Logic. Dr. E. Barclay-Smith has been appointed Senior Demonstrator, and F. C. Kempson Junior Demonstrator in the department of Anatomy. Dr. J. N. Keynes has been appointed by the Council of the Senate to act on the joint committee for promoting legislation on secondary education now sitting in London. Mr. Yule Oldham, University Lecturer in Geography, is this term lecturing on the geography of Central Europe, and also (in conjunction with Mr. J. E. Marr, F.R.S.) on the scientific study of scenery. The geographical classes have of late been larger than in any previous year, and Mr. Oldham is steadily gaining ground for his subject in the University. Certain changes in the Historical Tripos will lead students to devote more of their time to political geography, and a new section of the higher local examination deals with the wider aspects of the science. The studentship of 100*l.* offered by the Royal Geographical Society to members of the University attending his lectures, will be awarded at the end of the present term. Mr. W. Bateson, F.R.S., of St. John's College, is this term giving a special course of lectures on the study of variation, which he has made peculiarly his own. A Shuttleworth Scholarship of 55*l.* a year for three years will be awarded at Gonville and Caius College in March. The subjects are botany and comparative anatomy, and candidates must be medical students of not less than eight terms' standing.

LORD WANTAGE, Mr. Richard Benyon, and Mr. Herbert Sutton have each given 1000*l.* to the building fund of the University Extension College, Reading. Mr. G. Palmer, Mr. G. W. Palmer, Mr. W. Palmer, and Mr. A. Palmer have each contributed 500*l.* for the same object, and the Drapers' Company have promised 1000*l.* on condition that a sum of 12,000*l.* is raised without delay. The Hampshire County Council have voted 1000*l.* out of accumulated surplus for the foundation of exhibitions in connection with the College.

THE following are among recent announcements:—Dr. Wilhelm Valentiner, formerly director of the astronomical observatory at Karlsruhe, to be professor of astronomy at the University of Heidelburg, whither that observatory has been removed; Dr. v. Buchka has taken up his residence at Berlin as successor to the late Dr. Eugen Sell in chemistry; Mr. J. G. Luehmann, for many years assistant to the late Baron von Mueller in the Government Botanist's Department, to be curator of the Melbourne Herbarium; Prof. B. Hatsheck, of Prague, to the chair of zoology in the University of Vienna, vacant by the resignation of Prof. K. Claus; Prof. Th. Curtius, of Kiel, to be professor of chemistry at Bonn, in succession to the late Prof. Kekulé; Dr. P. E. Study, associate professor of mathematics at Bonn, to be professor of mathematics at Greifswald; Dr. G. A. Tawney, Princeton, to be professor of philosophy in

Beloit College, Wisconsin; Dr. S. Kalischer to be professor of physics in the Technical High School at Charlottenberg; Dr. W. Autenrieth to be provisional successor to the late Prof. Baumann in the chair of physiological chemistry in the University of Freiburg, in Baden.

AT the ordinary general meeting of Convocation of the University of London, on Monday, the report of the annual committee was adopted. The recommendations of a sub-committee, appointed to consider the possibility of rendering the library and laboratory of the University more available for general use, came up for discussion. A motion was carried expressing regret at the lack of a University Hall, which compelled the Senate to use the library for purposes for which it was not intended, and asking the Senate to consider whether steps could not be taken to remove the limitations which exist to the free use of the library. The sub-committee reported that the chemical and physical laboratories of the University are, *qua* laboratories, non-existent; but no remedies for these defects were suggested. It was pointed out that a complete and radical reorganisation is needed in the equipment of the University before its laboratories can be regarded as adequate for even the restricted purposes of examination, to say nothing of those of teaching or research. Indeed, the sub-committee doubts whether a laboratory equipped for the purpose of examination can properly be used for teaching or research. The Council of the Royal Botanic Society have offered a site, free of cost, for the erection of a students' observatory in connection with the University, together with the use of a lecture-room. The report of the annual committee adds that boards of studies in the subjects of physics, chemistry, botany, modern languages and literatures, mental and moral science, classics, political economy, and zoology are now actively engaged in the revision of the various syllabuses.

A STRONG committee, representing the leading associations concerned with technical and secondary education in this country, was formed last October to consider the ways and means of promoting legislation for secondary education. The committee has now unanimously adopted a number of resolutions, and submitted them to the Lord President of Council. Among the resolutions are the following: (*a*) In order to bring the State into a fitting relation to secondary education, it is necessary to provide for the constitution of a central authority suitable for this purpose (under a Minister of Education, when appointed), simultaneously with the provision of local educational authorities. (*b*) To this central authority should be transferred the powers and functions at present exercised by the Education Department and the Science and Art Department, so far as they relate to secondary education. In the opinion of this committee, it is of urgent importance that the Charity Commission should, as soon as possible, be included in the central authority, so far as its educational functions are concerned. (*c*) The central authority should include an educational council constituted on the principle laid down in the Teachers' Registration Bill of 1896, which council, in addition to the duties imposed on it in that Bill, might advise the Minister on the schemes for the constitution of local authorities and other matters referred to it by him. (*d*) There should be created a local authority for secondary education in every county or county borough, but in no areas smaller than these. Adjoining counties and county boroughs to have power to unite. (*e*) Scholarships and exhibitions should be tenable at, or open to the pupils of, any efficient school or institution; and this should not be regarded as aid to the school or institution within the meaning of the Act. (*f*) It is desirable that the legislation proposed should include a Bill, similar to the Bill of last Session, for the purpose of registering teachers qualified to teach in secondary schools, with this modification, that the third group of representatives of teachers on the registration council should be elected by persons not included in groups 1 and 2.

SPEAKING at a dinner given by the Drapers' Company, on Thursday last, to "meet the Lord President of the Council and the Incorporated Association of Head Masters," the Duke of Devonshire sketched the position of the Government with regard to secondary education. In the course of his remarks, he said:—"This would not, I think, be a fitting opportunity on which I should attempt to discuss the measure which I trust may at no distant date be introduced bearing upon this subject by Her Majesty's Government. But I think I may safely say that when the time comes when Parliament will be called upon to deal with this question a very considerable agreement will be found to exist as to the principles—the general principles—I will not say the details upon which it should be founded. I believe that the principles which have been laid down in the report of the Royal Commission on Education, which was published a year, or a little more than a year ago, have met as to their general lines—I refrain altogether from saying as to their details—with the general approval and the consent of those who have been concerned either in an administrative or a professional capacity with this subject. You will remember that those lines were, generally speaking, drawn in local rather than in centralised directions, and that while the necessity has been admitted for unifying and concentrating many of those educational forces, which are at present unduly and unnecessarily dispersed, the Commissioners have carefully borne in mind the necessity of doing nothing to injure that which they themselves have described as the rich variety of our educational life, or to impair the individual energy and activity which has actuated it. These are the principles which I believe and trust will underlie any measure which the Government may ultimately feel itself able to introduce. As to what needs to be done, there is first the necessity of remodelling the central authority, which probably may be done rather by administrative than by legislative methods, exercising powers which will be chiefly those of superintendence, revision, and advice, but for the exercise of which the central authority ought to combine the knowledge of endowed schools, of organised science schools, of science and art schools, of higher grade Board schools, which is now possessed by various and separate departments of the Government. Secondly, I think we are all pretty universally agreed that it is necessary to constitute some local authorities administering the secondary education over areas of sufficient extent; and, thirdly, something in the nature of an educational council ought to form part of the central authority, although it would have to exercise, not administrative, but purely consultative functions."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, January 11.—M. A. Chatin in the chair.—The Secretary announced to the Academy the loss it had sustained in the death of Dr. Gould, Correspondant in the Section of Astronomy.—Notice on the scientific work of Benjamin Apthorp Gould, by M. Lewy.—Researches on the composition of French and foreign wheat, by MM. Aimé Girard and E. Fleurent.—Observations on the periodic Brooks' comet (1889 *v*-1896 *c*), and the comets of Giacobini (1896 *d*), Brooks-Spéra (1896 *e*), Perrine (1896 *f*), and Perrine (1896 *g*), made with the longe equatorial of the Observatory of Bordeaux, by MM. G. Rayet, L. Picart, and F. Courty.—Remarks by M. Armand Gautier, on presenting to the Academy a copy of his work on normal and pathological biological chemistry.—Alimentary hygiene; red and white wine, by M. P. Carles.—Note on a project for crossing Central Europe by an aerostat, by MM. G. Besançon and E. Aimé.—The rarefaction of air in balloons, by M. O. Julien.—New nebulæ discovered at the Paris Observatory, by M. G. Bigourdan.—Observations on shooting stars of December 12, 1896, made at Athens, by M. D. Egenitis.—Remarks on the method of Gauss for the determination of the orbits of the small planets, by M. J. Perchot.—Distances of the solar system, by M. Delauney.—On the movement of a solid in an indefinite liquid, by M. R. Liouville.—Some remarks on a note by M. Delsol, entitled "On a thermic machine," by M. H. Pellat. The reasoning in question would make the machine described of higher efficiency than that given by the application to the case of the second law of thermodynamics. Two objections are raised to the arguments given by M. Delsol.—On the variation of the melting point with pressure, by M. R. Demerliac. The rate of change of melting point with pressure has been experimentally studied for paratoluidine, and for α-naphthylamine. The values obtained are in complete agreement with those given by the formula of Clapeyron, involving the latent heat of fusion and change in the specific volume.—On the absolute value of the magnetic elements on January 1, 1897, by M. Th. Moureaux.—On the density of ozone, by M. Marius Otto. The same flask was filled successively with dry oxygen and ozonised oxygen, and weighed, the amount of ozone present being after determined with suitable precautions by means of an

acidified solution of potassium iodine. The density found was that of oxygen, within the limits of experimental error.—Decomposition of metallic sulphates by hydrochloric acid, by M. Albert Colson.—On the polymerisation of some cyanic compounds, by M. Paul-Lemoult. Correcting some thermochemical calculations given in a previous note.—Dimorphism of the optical isomerides of the succinates of camphol, by M. J. Minguin.—Action of potassium cyanide upon the 1 : 4 lactones, by M. Edmund Blaise.—Phosphoric ethers of allyl alcohol, by M. J. Cavalier.—On a difference between high and low yeasts, by M. P Petit. The two kinds of yeast show differences in their behaviour towards nitrogenous foods.—Contribution to the study of the coagulating ferment of the blood, by MM. A. Dastre and N. Floresco.—Refractory period in the nervous centres, by MM. André Broca and Charles Richet.—Evolution of the Monstrillidæ, by M. A. Malaquin.—On the relations existing between the *Discopoma comata* (Berlese) and *Lasius mixtus* (Nylander), by M Charles Janet.—On the development of the white rot in the vine (*Charrinia diplodiella*), by M. P. Viala.—The Swiss Rhone tributary of the Rhine, by M. Maurice Lugeon.—On the differential equations of the second order, with several independent variables, by M. A. J. Stodolkiewitz.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 21.

ROYAL SOCIETY, at 4.30.—On Cheirostrobus, a New Type of Fossil Cone from the Calciferous Sandstone: Dr. D. H Scott, F.R.S.—(1) Experiments in Examination of the Peripheral Distribution of the Fibres of the Posterior Roots of some Spinal Nerves, Part II.; (2) Cataleptoid Reflexes in the Monkey; (3) On Reciprocal Innervation of Antagonistic Muscles (third note): Prof. Sherrington, F.R.S

ROYAL INSTITUTION, at 3.—Some Secrets of Crystals: Prof. H. A. Miers, F.R.S.

LINNEAN SOCIETY, at 8.—On the Origin of the Corpus callosum; a Comparative Study of the Hippocampal Region of the Cerebrum of Marsupialia and certain Cheiroptera: Dr. G. Elliott Smith.—On the Minute Structure of the Nervous System of the Molluscs: Dr. J. Gilchrist.

CHEMICAL SOCIETY, at 8.—Studies of the Properties of Highly Purified Substances. I. The Influence of Moisture on the Production of Ozone from Oxygen and on the Stability of Ozone. II. The Behaviour of Chlorine, Bromine, and Iodine with Mercury. III. The Behaviour of Chlorine under the Influence of the Silent Discharge of Electricity and in Sunlight: W. A. Shenstone.—Action of Diastase on Starch, Part III.: A. R. Ling and J. L. Baker.—The Solution Density and Cupric-reducing Power of Dextrose, Levulose, and Moist Sugar: H. Trace T. Brown, F.R.S.; Dr. G. Harris Morris; J. H. Millar.—Derivatives of Maclurin, Part II.: A. G. Perkin.

GRESHAM COLLEGE, at 6.—Milk, Meat, and Oysters as Carriers of Disease: Dr. Symes Thompson.

FRIDAY, JANUARY 22.

ROYAL INSTITUTION, at 9.—Properties of Liquid Oxygen: Prof. Dewar, F.R.S.

PHYSICAL SOCIETY, at 5.—An Exhibition of some Simple Apparatus by W. B. Croft.—On the Passage of Electricity through Gases: E. C. Baly.

GRESHAM COLLEGE, at 6.—Diphtheria: Dr. Symes Thompson.

SUNDAY, JANUARY 24.

SUNDAY LECTURE SOCIETY, at 4.—Life on the Surface of Water: Prof. L. C. Miall, F.R.S.

MONDAY, JANUARY 25.

SOCIETY OF ARTS, at 8.—Material and Design in Pottery: W. Burton.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—An Expedition across Spitzbergen: Sir W. Martin Conway.

INSTITUTE OF ACTUARIES, at 7.—Rates of Mortality in certain Parts of Africa: A. E. Sprague.

CAMERA CLUB, at 8 15.—The Zamanass for Registering High Velocities: Sir C. Purcell Taylor, Bart.

TUESDAY, JANUARY 26.

ROYAL INSTITUTION, at 3.—Animal Electricity: Prof. A. D. Waller, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Diversion of the Periyar: Colonel J. Pennycuik, R.E.

ANTHROPOLOGICAL INSTITUTE, at 8.—Anniversary Meeting.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Architectural Photography: Ernest Marriage.

WEDNESDAY, JANUARY 27.

BRITISH ASTRONOMICAL ASSOCIATION, at 5.

THURSDAY, JANUARY 28

ROYAL SOCIETY, at 4 30.—The following Papers will *probably* be read:—On the Capacity and Residual Charge of Dielectrics as affected by Temperature and Time: Dr. J. Hopkinson, F.R.S., and E. Wilson.—On the Electrical Resistivity of Electrolytic Bismuth at Low Temperatures and in Magnetic Fields: Prof. Dewar, F.R.S., and Prof. Fleming, F.R.S.—On the Selective Conductivity exhibited by certain Polarising Substances: Prof. J. C. Bose.

ROYAL INSTITUTION, at 3.—Some Secrets of Crystals: Prof. H. A. Miers, F.R.S.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Electrical Interlocking, the Block, and Mechanical Signals on Railways. F. T. Hollins.

FRIDAY, JANUARY 29.

ROYAL INSTITUTION, at 9.—The Polarisation of the Electric Ray: Prof. J. C. Bose.

INSTITUTION OF CIVIL ENGINEERS, at 8.—An Experimental Investigation of the Efficiency of a Pelton Waterwheel: S. Henry Barraclough.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

BOOKS.—Onorante al Prof. S. Cannizzaro. Rediconto Generale (Roma).—Smithsonian Physical Tables: T. Gray (Washington).—The Practical Photographer, Vol. 7 (Lund).—Our Weights and Measures: H. J. Chaney (Eyre).—An Introduction to the Study of Chemistry: Drs. W. H. Perkin and B. Lean (Macmillan).—Colliery Surveying: T. A. O'Donahue (Macmillan).—Fruit Culture for Amateurs: S. T. Wright (Gill).—The Hemiptera-Hemoptera of the British Islands: J. Edwards (L. Reeve).—Black-board Drawing: M. Swannell (Macmillan).—Microscopic and Systematic Study of Madreporarian Types of Corals: Dr. M. M. Ogilvie (Dulau).—Among British Birds in their Nesting Haunts: O. A. J. Lee, Part 2 (Edinburgh, Douglas).—Den Norske Nordhavs-Expedition, 18-6878. xxii. Zoologi, Tunicata: A. Huitfeldt-Kaas (Christiania, Grondahl).—A Manual of Elementary Seamanship: D. Wilson-Barker (Griffin).—Getting Gold: J. C. F. Johnson (Griffin).—Pioneers of Evolution from Thales to Huxley: E. Clodd (Richards).—Travels in West Africa: Mary H. DARWIN AND DARWINISM.

Charles Darwin and the Theory of Natural Selection. By Edward B. Poulton, M.A., F.R.S., F.G.S., F.L.S., &c., Hope Professor of Zoology at the University of Oxford. Pp. 224. (London, Paris, and Melbourne: Cassell and Company, Ltd., 1896.)

AFTER the one-volume "Life and Letters" by Francis Darwin, and the admirable little book by Grant Allen in the "English Worthies" series, there seemed to be little room for another English work upon the same subject; yet the present small volume is markedly original, and while following pretty closely the general lines of the "Life and Letters," introduces much new matter, and gives a fuller account of what may be termed the critical points of Darwin's theories than are to be found in any of the works here referred to. It is written in a thoroughly sympathetic, though impartial, spirit; and without introducing any actual criticism, either of the views of Darwin or of his opponents (which would have been manifestly out of place in a popular work), it yet makes clear the differences of opinion that now exist as to some of Darwin's most cherished theories, and, while briefly stating the main facts and hypotheses on both sides, leaves the reader in no doubt, both as to the exact nature and importance of the opposing views and the kind of evidence that is required in order to decide which is most in accordance with the facts of nature.

The first seven chapters deal with Darwin's life down to the year 1856, the facts of which are so widely known that they call for no special notice. Though much condensed, they supply all the information needed by the general reader; and we will only quote the following estimate of character as due to heredity, which is very suggestive:

"It appears probable that Charles Darwin's unique power was largely due to inheritance of the imagination of his grandfather, combined with the acute observation of his father. Although he possessed an even larger share of both these qualities than his predecessors, it is probable that he owed more to their co-operation than to the high degree of their development."

While believing this estimate to be generally correct, it appears to the present writer that two other important factors have been usually overlooked—the solitude of the five years' voyage and the persistent ill-health. During a very large portion of the five years with the *Beagle*, Darwin must have been practically alone and thrown on his own mental resources, not only on the ship when all the officers would be engaged on their duties, but during his numerous land-journeys and excursions on shore; and this mental solitude of an active mind, furnished continually with new and interesting facts on which to exercise the imaginative and reasoning powers, led to the formation of those original and suggestive ideas which were the foundation of his greatness. Hardly less important was the almost continuous ill-health, which, while not preventing work or shortening life, obliged him to live in the country, free from the distractions of society, and where his active mind could only be satisfied by continual study and experiment. Without the solitude of the voyage the fundamental idea of natural selection might never have been attained; with vigorous health that wonderful series of experimental observations in the quiet and solitude of Down, without which the "Origin of Species" would have lost much of its convincing power, would almost certainly not have been made.

Chapters viii. to xii. are devoted to the relations between Darwin and the present writer, about which nothing need be here said, except that they contain some new matter, and while too flattering to myself, appear to be quite accurate as to the facts.

The next six chapters are devoted to a sketch of the writing and publication of the "Origin," and the influence of Darwin upon his more eminent friends and correspondents; and of these chapters the most original and important is the eighteenth, on the "Influence of Darwin upon Huxley." Prof. Poulton here points out the misconceptions prevalent as to Huxley's exact views, showing that the one and only point on which he considered the theory to fail in logical completeness was the absence of proof of infertility arising among the most divergent races of domestic animals, a difficulty which still exists, but which may possibly be set at rest by systematic and long-continued experiment. This difficulty, however, applies equally to all other theories; while, if the argument of the present writer is sound—that, under certain conditions which are frequently present, the variations in fertility which undoubtedly occur will be accumulated by natural selection, we not only have the general occurrence of infertility between allied species explained, but we also see why such infertility does not arise among varieties due to man's selection, since he has never attempted to produce it. A more thorough examination of this problem seems, therefore, to be called for.

Chapters xix. and xx. are devoted to an interesting exposition of the various misconceptions and misrepresentations of the theory of natural selection, which caused so much trouble and annoyance to Darwin, misconceptions which are still prevalent, as shown by Lord Salisbury's recent address, and by passages in Prof. Cope's last book (see NATURE, vol. liii. p. 554). These chapters are therefore very opportune, and may do something to show the public that a large proportion of Darwin's critics have not taken the trouble to understand the theory to which they take exception.

The next two chapters are perhaps the most original and important in the volume, since they contain a very careful summary of Darwin's celebrated theory of Pangenesis. To most of the readers of this work these chapters will be entirely new, and will give them in a very readable form some idea of the exceedingly varied and complex phenomena of "inheritance" which the theory was formed to explain. Among these are sexual and asexual reproduction, the complex phenomena of variability and inheritance, the diversity of embryonic changes during development of allied groups, the phenomena of graft-hybrids, the reproduction of lost parts, the sterility of hybrids, reversion to ancestral forms, and many others. Besides these there are the

doubtful phenomena of the inheritance of the effects of use and disuse and of other acquired modifications of the individual by external conditions, which Darwin accepted as a fact, though he remarked upon it: "Nothing in the whole circuit of physiology is more wonderful."

Every one who reads this account of Pangenesis will feel admiration for its ingenuity, and surprise at the completeness with which it can be made to explain all the varied phenomena of inheritance, though some of these explanations seem more verbal than real. Readers will also understand the fundamental difference between this theory and that of Weismann; and will see, that in order to decide which best explains the whole series of phenomena, the inheritance or non-inheritance of acquired characters, as a matter of fact, must first be settled.

The difficulty of conceiving the actual operation of the theory of Pangenesis may be best illustrated by an example. Taking a bird, such as a peacock, the theory implies that not only every cell and fibre of bone, muscle, skin, and all internal organs gives off gemmules which all find their way into every one of the cells constituting the sperm or reproductive fluid, but that every one of the feathers also sends gemmules from each of the cells that build up its wonderfully complex structure, not only in the adult stage, but in the condition they assume in the young and adolescent birds; and further, that every detail of varying colour of the barbs of these feathers send off their gemmules, and that all this inconceivable number of gemmules must travel through the whole structure of the quill, and through all the tissues of the body, till they reach the reproductive organs, and every one of these gemmules must reach all or most of the sperm-cells, failing which there would be a corresponding deficiency in the offspring. But as important deficiencies of feathers, or of colour on the various feathers, which produce the beautiful patterns and ornaments of a bird's plumage only rarely occur, we must assume that the passage of the millions of gemmules from the ends of the feathers of a peacock's train through the whole length of the shaft, and then to the sperm-cells, is almost always successfully accomplished. In addition to the enormous difficulty, on any theory, of conceiving the processes of growth and development of the complex parts of living organisms, we have, on this theory, an equal or greater difficulty in the reverse process, by which the gemmules from every cell get back again to the sperm and germ cells. Without asserting that this process is impossible or inconceivable, it is well to endeavour to realise what it really is and its almost incredible complexity.

Prof. Poulton gives a brief account of the experiments made by Mr. Galton and the late Mr. Romanes to test the theory of Pangenesis, by the transfusion of blood and the transplantation of skin, from one variety of animal to another, and then breeding from the modified individuals; but in no case was any effect produced on the characters of the offspring. Though, perhaps, not quite conclusive, these experiments indicate that there is no such continuous transference of gemmules as the theory requires.

The remaining three chapters deal with the descent of man and sexual selection, the various botanical works, and a series of hitherto unpublished letters to Prof. Meldola, chiefly interesting as illustrating Darwin's kindness to all students of natural history, and the amount of trouble he took to be of use to them.

On the whole, Prof. Poulton is to be congratulated on the production of so interesting a book, which in a wonderfully limited space gives a connected account of Darwin's life and work, and especially of some portions of his theories which have been almost neglected by other writers. A good print, from a photograph, of Darwin's statue in the Natural History Museum, forms the frontispiece of the volume.

ALFRED R. WALLACE.

LIFE OF BRIAN HOUGHTON HODGSON.

Life of Brian Houghton Hodgson, British Resident at the Court of Nepal. By Sir William Wilson Hunter, K.C.S.I., M.A., LL.D. Pp. 389, 8vo. (London: John Murray, 1896.)

IN this charming volume Sir William Hunter has compiled a worthy memorial of one of the most famous of our Indian civilians, one of the very few who have been able to rise above the details of their daily work, and to take a real intellectual interest in the history or the science of the strange people and lands in which their life is cast.

Born in 1800, young Hodgson, who had influential relatives, was in 1816 offered a nomination to the East India Company's service, and entered Haileybury College, where all the civilians were then trained. Malthus was then Professor of Political Economy in the college, and happened to be an old college friend of an intimate friend of the Hodgsons. Advantage was taken of this to introduce the new scholar, and Malthus not only made him his guest during the first session, but remained throughout the lad's college residence his constant friend. Henry Walter had also just joined the college as Professor of Chemistry and Natural History, and Sir James Mackintosh became Professor of Law two years afterwards. No doubt the future scholar and collector owed very much to the teaching of Malthus and Walter, and to the personal friendship of the former; though the traces of their influence on any other of the collegians of the time are not conspicuous.

In December 1817 Hodgson passed out of Haileybury as gold medallist and head of his term, and sailed in the following year, round the Cape, to Calcutta. Sir Charles D'Oyly, the Controller of Customs, a connection of Hodgson's family, and a man of much artistic and literary culture, welcomed him, and made his house his home. Not only were the D'Oylys leaders in Calcutta society, but Sir Charles had only lately brought out a book on the antiquities of Dacca. And it was through the influence of Lady D'Oyly, a near connection of the Governor General's, that young Hodgson was shortly appointed assistant to the Commissioner of Kumaun—one of those appointments in the hills, then very few in number, reckoned among the prizes of the Service.

Kumaun had only just been taken from Nepal by the English; and the duties of the new Assistant consisted chiefly in helping to make a revenue settlement in the new province. The fine air of those lofty valleys soon

restored his health, which had seriously suffered in Calcutta. Both his duties and his sport brought him into close contact with the people. But he was not to remain there long. In 1820 the Assistant-Resident at the Court of Nepal died, and Hodgson succeeded to the post. Two years afterwards he returned for a short time to the Secretariat in Calcutta, but in 1825 he was re-appointed to the Assistant-Residentship in Kathmandu. In 1833 he became the Resident, and remained in that appointment until he left the Service in 1843.

The daily duties of such a Resident at an independent Court are, in quiet times, not onerous. But now and again, when in the never-ceasing struggles of palace intrigue the anti-English feeling, naturally always existing, comes to the front, the position of Resident becomes suddenly of importance; his work becomes all-absorbing, and constant demands are made upon his judgment, his tact, and even occasionally upon his personal bravery. Sir William Hunter is an excellent guide through the intricacies of the palace cabals, and sets out the dismal story of the deposition, exile, or murder of successive nominal rulers, and of the rise to power of the real rulers, the mayors of the palace, three out of four of whom came also to a violent end. Throughout these crises it was acknowledged on all hands (with one exception) that Hodgson conducted the necessary negotiations with wisdom, tact, and courage beyond praise. But that exception was the Governor General. When he was convinced, at last, that the Resident was acting less on the orders given than on his own view of the position, Lord Ellenborough dismissed him from his post, and offered him a minor appointment in Simla. This the sensitive spirit of Mr. Hodgson could not brook, and he resigned the Service in 1843.

During his long service at Kathmandu the Resident had never lost an opportunity of adding to his wide knowledge of the history of the zoology of Nepal and Tibet. And when he was thus forced out of the Service, his name was already known and honoured throughout the world. Nepal had been for centuries an asylum for the Buddhism which had died out in its original home in the valley of the Ganges. There and there alone are to be found those Sanskrit Buddhist MSS. on which the Buddhism, not only of Nepal itself, but of Tibet and China, of Japan and the Korea, is based. No less than 423 of these otherwise inaccessible records of the Buddhist movement were either bought or copied by Hodgson, not for himself, but in order that, with a generosity as unequalled as was his intellectual ardour, they might be presented either to the Asiatic Society in Calcutta, or to similar learned bodies in England and France. So far as it was possible for one, not himself a Sanskrit scholar, to discuss or elucidate the problems of the history of the ancient faith of Buddhism, he endeavoured to do so, and spared neither trouble nor expense in gathering from the *pandits* of the Nepal capital such knowledge as they possessed. This he communicated, from his solitary outpost in the hills, to the Asiatic Society of Bengal; and these results of his researches in what was then an almost unworked field aroused the enthusiastic appreciation of scholars throughout the world. He had hoped that the MSS. he presented would enable Sanskrit scholars to carry on, from the original sources, the researches he had thus begun from the mouths of living witnesses. In only one instance were his hopes realised. The MSS. he sent to Paris lured Eugène Burnouf from his other pursuits, and led him to devote his genius and scholarship to those studies in early Buddhism which really laid the foundation of all we now know on the subject. (His first great work on Buddhism is dedicated to Hodgson.) Nearly half a century elapsed before even a catalogue appeared of the Hodgson MSS. in Calcutta, and that is an inaccurate and unsatisfactory work. The much better catalogue, entirely trustworthy, so far as it goes, of the Hodgson MSS. in the Royal Asiatic Society, had appeared a few years before. But no English scholar had worked at them. It is only in the last few years that they are beginning to be a little utilised, to be appreciated at their right value. Foreign scholars have devoted themselves to the work; and notably M. Senart in Paris has taken up, in a masterly manner, the work left unfinished by the premature death of Burnouf. So year after year the gratitude of historical students will go out in increasing measure to the enlightened generosity of the scholar who has provided for their use the largest body of original documents on Buddhism which, up to his time, had ever been gathered together either in Asia or in Europe—documents whose very existence had been previously unknown.

When he left the service, Hodgson, after a short stay in England, settled in Darjiling, and began then to take up seriously a quite different branch of historical inquiry in which he had also been always interested. This was the very complicated question of the non-Aryan races of the Himalayan valleys. He contributed numerous papers on the language, religion, customs, and social condition of these tribes to the Asiatic Society of Bengal. His work in this field of inquiry was not only that of a bold pioneer, who laid down with admirable judgment the right method of inquiry, but has also remained in most instances till to-day the best that has been done, and, with regard to almost all the tribes with which he dealt, it is the foundation of all subsequent work. As year by year the importance of the non-Aryan element in all questions relating, not only to the physique, but also to the history of the religious and social ideas of the Indian peoples, becomes more and more recognised, the value also of this branch of Hodgson's researches has been more and more appreciated. It was fully acknowledged at the time by those most competent to judge, and he was elected an Honorary Fellow of the Ethnological Society—a distinction then shared, amongst Englishmen, only by Darwin, Layard, and Rawlinson.

Meanwhile, during the whole time of his residence in India, Hodgson never lost his interest in what was then called natural history. He wrote no less than eighty papers for scientific societies (mostly for the Bengal Asiatic Society) on the Himalayan mammals, and contributed more than any one else, except only Blyth and Jerdon, to our knowledge of the birds of India. Though his opportunities were confined to two of the smaller districts, he added fully a hundred good new species to the Avi-fauna of British India. "He trained Indian

artists," says Hume (whose joint work with Marshall on the "Game Birds of India" is dedicated to Hodgson), "to paint birds with extreme accuracy from a scientific point of view; and under his careful supervision admirable large scale pictures were produced, not only of all these new species, but also of several hundred others, and in many cases of their nests and eggs also. These were continually accompanied by exact, life-size, pencil drawings of the bills, nasal orifices, legs, feet, and claws (the scutellation of the torso and toes being reproduced with photographic accuracy and minuteness), and of the arrangement of the feathers in crest, wing, and tails." Unrivalled as a collector, Hodgson's generosity with his specimens and drawings was equally unrivalled, and practically the whole of them were given to public libraries or scientific societies.

We would not have the appreciation which his biographer has lavished upon his many-sided intellectual activity diminished by a single word. It is only strange that the marked absence of anything of the kind in other civilians should not have seemed to Sir William Hunter to call for any limitation of that exuberant optimism with which he regards the ways and works of every official (except Lord Ellenborough) that he has to mention. No doubt the results of the system of Indian government have been, from a material point of view, encouraging. The members of the Service have developed administrative qualities of a high order. But is there nothing at all that is lacking? Is not intellectual alertness sometimes smothered under a mass of detail, and any really scholarly or scientific knowledge tabooed or discouraged as waste of time? And is not the best executive ability apt to strike cold when it wants the charm of intellectual sympathy? Nothing is more evident in this book than the way in which Brian Houghton Hodgson's wide knowledge and intellectual sympathy helped him in his official work, unless indeed it be the degree in which, in those qualities, he stood alone. We need not wonder that he received from the Indian Government none of those titular honours that were bestowed on many of his contemporaries, now forgotten.

The biography is delightfully and lucidly written, and enriched by contributions from specialists in the various subjects dealt with in Hodgson's works. The charm of the narrative is such that the reader will probably find it only too short. And a word of acknowledgment must be given to the beauty of the illustrations, especially of the striking picture taken by Mrs. Hodgson, to whom the work is dedicated.

OUR BOOK SHELF.

Manual of Determinative Mineralogy, with an Introduction on Blowpipe Analysis. By G. J. Brush. Revised and enlarged by S. L. Penfield. Pp. vi + 208. (New York: Wiley. London: Chapman and Hall, Ltd., 1896.)

THE manual of the veteran mineralogist, and present Director of the Sheffield Scientific School at New Haven, has been in constant use since 1874, and has passed through thirteen editions. The present volume is the beginning of a new and revised edition which has been undertaken by Prof. Penfield. The determinative tables, originally based upon von Kobell's "Tafeln zur Bestimmung der Mineralien," remain as they were in the thirteenth edition, but they are now preceded by four chapters on the qualitative analysis of minerals, which have been in great part re-written by Prof. Penfield. These chapters are, as might be expected from this able mineralogist, entirely excellent. The description of the apparatus and methods employed is most simple and clear, and is rendered attractive by numerous good illustrations, which are in large part new.

The book abounds in practical hints of the greatest value to a beginner. The course consists of a series of simple experiments so arranged as to illustrate the reactions of the various elements, and many of these are designed to illustrate the *difficulties* which attend their use, and the risk of drawing erroneous conclusions, *e.g.* "The mistake is sometimes made of testing carbonates with acids which are too concentrated, as illustrated by the following experiment," &c.; or again, "In order to show that there is sometimes danger of overlooking a small quantity of a carbonate, test as follows."

The rarer elements are treated, as well as those which the student is more likely to encounter, and due regard is paid to newly-discovered reactions. Thus mention is made of the method of testing recommended by Haamel, in which the material is heated in the oxidising flame after being moistened with hydriodic acid, or tincture of iodine, as suggested by Wheeler and Luedeking; and it is recommended that a plaster of Paris tablet should be used to collect the coloured sublimates produced. It is perhaps unfortunate that this method does not find a place in the summary of blowpipe and chemical reactions, which constitutes Chapter iv.

The fundamental principles of qualitative analysis (*e.g.* the nature of the flame, and the action of charcoal) are more fully explained than in the preceding editions; and for these and other reasons, the volume is a more satisfactory handbook for an elementary student than any with which we are acquainted.

The new edition is to be completed by the revision of the determinative tables, and Prof. Penfield promises to add to these a chapter on crystallography and the physical properties of minerals. It is, we think, to be regretted that the publishers have brought out the new edition in an incomplete state.

Grundriss der Entwicklungsgeschichte des Menschen und der Säugethiere. By Dr. Oscar Schultze. Erste Hälfte. Pp. 177. (Leipzig: Engelmann, 1896.)

THIS work, which is a revision of Prof. Koelliker's book, is intended especially for students and practitioners. Although Dr. Schultze writes his descriptions of the various developmental processes in a concise manner, avoiding controverted and purely theoretical points as far as possible, still he has introduced into his book all the more recent important observations on mammalian embryology. The work appears to be throughout in all points quite up to date. The well-chosen figures, which are numerous and nicely reproduced, are all taken from mammalian embryos, and it will doubtless be a satisfaction to a student of human embryology to find such illustrations instead of the oft-repeated figures of fowl, reptile, and even invertebrate embryos common in text-books on human development. Our present knowledge of the early stages of mammalian embryos quite justifies the omission of such figures in an account of mammalian development. Dr. Schultze has succeeded in making his history of the embryology of man and mammals hang well together. As the work is sure to be extensively used, it is to be hoped that an English translation will shortly be forthcoming. The second part is promised at the end of this year.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Oyster Question.

PROF. THORPE'S allusion to myself in connection with oysters and their ways in a recent[1] number of NATURE (p. 106) has reminded me that I also have something to say on the subject, *à propos* of the "Yellow Book" issued by the Local Government Board.

First, I wish to state that several references to my work, made in that and other recent publications on oysters and disease, ought rather to be to the work of my colleague Prof. Boyce, or to our joint work.

In conjunction with Prof. Boyce, I have published three notes on the subject, and the bacteriological parts of these have, naturally, been contributed by my colleague. The first note was read (and circulated) at the Ipswich meeting of the British Association in September 1895, the second was brought before the Liverpool Biological Society in January 1896, and was published that same month in the Annual Report of the Lancashire Sea Fisheries Laboratory for 1895, while the third was read (by Prof. Boyce) to Section I at the Liverpool meeting of the British Association last September, and reprints have since been circulated. The points that we believe we have demonstrated (I do not say that they were all new when announced—some were known, others suspected, some denied; but I think we have given definiteness to all) are as follows:—

(1) The beneficial effect of free change of water round the oysters.

(2) The deleterious effect of keeping the oysters in stagnant water.

(3) The considerable toleration of sewage shown by the oyster, and its power of absorbing large quantities of fecal matter.

(4) The great increase (*e.g.* from 10 colonies to 17,000 per sample) in the bacterial contents of the pallial cavity and of the rectum when the oyster is laid down in close proximity to the mouth of a drain.

(5) The presence of more bacteria in the pallial cavity than in the alimentary canal of the oyster.

(6) The fact that the typhoid bacillus does not flourish in sea water. There is no initial or subsequent multiplication; on the contrary, it seems to die off very rapidly as time increases after inoculation.

(7) The fact that the typhoid bacillus does not multiply in the stomach or tissues of the oyster.

(8) The presence of a "pale green" disease, characterised by a leucocytosis, in certain oysters.

(9) The fact that the dark blue-green colour of the Marennes oysters has nothing to do with copper.

(10) The fact that perfectly fresh oysters contain fewer bacteria than those that have been stored or kept in shops.

(11) The enormous number of the common colon bacillus present in very many oysters obtained from shops.

(12) The possibility of getting rid of bacterial infection by placing the oyster in a stream of running water. There is a great diminution or total disappearance of the *B. typhosus* under these circumstances in from one to seven days.

Perhaps it is on the last of these conclusions that Prof. Thorpe has founded his remark, that the oyster has confided to us its preference for clean water. Whatever it may *prefer*, Dr. Bulstrode has abundantly demonstrated in his report, that the oyster is not always *found* in clean water; and the practical conclusion of all these investigations and reports ought to be the enforcement of the two sanitary measures which Prof. Boyce and I recommended a year ago, viz. "(1) the strict examination of all grounds upon which oysters are grown or bedded, so as to ensure their freedom from sewage, and (2) if practicable, the use of "dégorgeoirs" in which the oysters should be placed for a short time before they are sent to the consumer"[2] ("Rep. Lanc. Sea-Fish. Lab." 1895, p. 72).

I am interested to see that Dr. Bulstrode (in the Local Government Board Report) independently corroborates our discovery of a pale green disease in some relaid oysters in this country. This is especially important, since Dr. Carazzi, of Spezia (whose results differ from those of most other investigators of molluscan structure and physiology), in a recently published paper, has doubted the existence of this green disease—probably because he has never met with it. He has drawn his conclusions mainly from the normal green Marennes oyster. We distinctly stated that the pale green disease had nothing in common with the dark blue-green of the "huitres de Marennes," and that we regarded the latter as being healthy and normal.

It is evident, then, that there are several distinct kinds of greenness in oysters. All recent investigators are agreed (except, possibly, Dr. Carazzi—I cannot venture to answer for him) that the green colour of the Marennes oyster has nothing to do with copper. Prof. Boyce and I have shown, and Dr. Bulstrode supports it, that the green of the (*e.g.* Fleetwood) relaid American oyster is due to a disease or leucocytosis, while now Prof. Thorpe tells us that (as was originally supposed, and then doubted) the greenness of the Falmouth oyster is really due to copper.

W. A. HERDMAN.

Liverpool, January 9, 1897.

P.S.—In connection with the correspondence which has taken place in NATURE, since Prof. Thorpe's article, I am glad to be able to add my testimony to that of Dr. Cartwright Wood and others as to the purity and healthy state of the Pyfleet oyster. I have visited the locality, have seen the oysters dredged up, and have examined (both biologically and gastronomically) many specimens, with entirely satisfactory results.

The Symbols of Applied Algebra.

I AM glad to see that attention is being forcibly drawn to the value and importance of considering the symbols in physical equations as primarily denoting quantities, and not mere numerical multiples of some unincluded standards. The latter mode of considering them, though often practically convenient, is entirely subsidiary, and a deduction from the primary equations between the quantities themselves.

The equation $w = mg$ is a special case of Newton's second law; it represents a fact of nature, and has nothing to do with systems of units. It is true in any units:—*e.g.*

$$981 \text{ dynes} = 1 \text{ gramme weight} = 1 \text{ gramme-mass} \times 32{\cdot}18 \text{ ft./(sec.)}^2.$$

The curious discussion about so simple an equation is kept up by those who wish to make all equations numerical only. To do this they must have a system of standards or units which themselves satisfy the equation. The numerical coefficients will then also satisfy the same equation, and the standards or units may be cancelled or omitted. The metric system has acquired the desired units by the invention of the dyne; and to do the same for the British system requires one of three alternatives:—(1) To take as unit of mass 32·18 lbs. or (say) a "perry," instead of 1 lb.; (2) to take g (32·18 ft./(sec.)^2) as unit acceleration; or (3) to employ a special unit of force, based directly upon Newton's second law, and upon the pound, the foot, and the second. Any of these conventions will serve: they are only needed for arithmetical interpretation of the equation, and, of them, the last is, on the whole, the simplest for general application, besides being in accordance with the universally adopted metric convention.

ALFRED LODGE.

Coopers Hill, January 18.

PROF. LODGE gives the formula $s = \frac{w}{v}$ as connecting the weight, volume, and specific gravity of a body. Does he seriously suggest that this is "independent of every system of units"? Surely it requires that the unit of weight should be the weight of unit volume of the standard substance. Would he give this formula to a student who measured forces in poundals?

The formula neatly illustrates the objection to the poundal. The C.G.S. system is theoretically perfect; the system in which the pound is the unit of force is, no doubt, theoretically objectionable, but is practically extensively used.

[1] This letter was written before the Christmas vacation, but has been delayed by examination and other engagements.

[2] Probably the most satisfactory method for all concerned—producers, customers, and sanitary authorities—would be to have all oyster beds, parks, layings and ponds inspected and "licensed," and to have no oysters exposed for sale except such as come from a certified locality.

The "poundal" system is equally objectionable theoretically (witness Prof. Lodge's formula $s = \frac{w}{v}$), and is not in practical use.

Then why introduce it? C. S. JACKSON.

Conductorless X-Ray Bulbs and Tubes.

IN October 1896 (NATURE, vol. liv. p. 594), a description was given by me of an exhausted bulb used in conjunction with a Tesla coil which gave X-rays and its photographic effects. Since these experiments I have found other phenomena, which throw some light on the relative positions of the conductor carrying the oscillations and the greenish fluorescence within the bulb or tube. The relationship is shown in the following diagrams :—

(1) A B is the conductor, with its axis parallel with O X, carrying the oscillating current of the Tesla secondary coil; S S the exhausted sphere, F D E a ring of greenish fluorescence, the plane of the ring being at right angles to the axis of the conductor A B. The X-ray effects were strongest at D, a point in O Y furthest from the conductor A B. The limits of the position of the edges of the fluorescence were easily traced by means of a minute fluorescent screen, placed at the end of a vulcanite tube, furnished with a cup-shaped end to cover the eye.

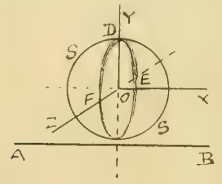

FIG. 1.

When the sphere was rolled, or moved parallel with itself along the length of the conductor, the plane of the glow-ring, F D E, kept its original position and moved perpendicular to the conductor. I have not been able to obtain the effects from an ordinary induction coil giving an 8 cm. spark only with the Tesla coil.

An exhausted tube was next placed within an open coil carrying the Tesla oscillations; the following beautiful effects were produced.

A B, exhausted tube; C C C, the spiral conductor; D D D, the glow in the form of a spiral within the tube. When the glass tube was about 4 mm. internal diameter, and the conductor, a gutta-percha covered copper wire, touched the glass, the spiral glow was very bright, and the glass became warm.

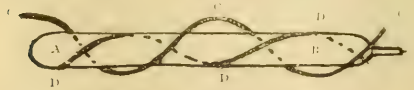

FIG. 2.

If a cross section be made through the tube and wire at right angles to the axis of the tube, a point in the glow is situated 180° from a point in the conductor, the section of the axis, the central point, being taken as the origin. The Tesla spark in air was 5 mm. long, and the coil formed a part of the spark circuit.

Oxford, January 14. FREDERICK J. SMITH.

Patterns produced by Charged Conductors on Sensitive Plates.

IN reply to the request of Mr. J. I'Anson for a reference to any former observations on the interesting effects described in your current number, he will find in the B.A. Report for 1888, and more fully in the *Philosophical Magazine* for December of that year, an account of the phenomenon as observed by the present writer, using cut-out patterns of tinfoil as conductors. This action of electrified conductors in contact with the photographic film was subsequently employed in a refined way by Rev. F. J. Smith, in making very beautiful and interesting prints from electrotype and other printing blocks. His results were shown at a conversazione of the Royal Society on May 10, 1893.

My own paper was chiefly occupied with a description of the figures produced by allowing sparks from an induction coil to play in various ways over photographic plates; and now that induction coils have become so much more widely distributed, it seems worth while to again draw attention to the exceedingly beautiful and interesting effects easily produced in this way.

A very fine set of prints from similar spark traces was exhibited by Mr. A. A. C. Swinton, at the Royal Society's conversazione of June 15, 1892. J. BROWN.

Belfast, January 22.

The Problem of the Sense Qualities.

(1) IN his very friendly notice of my "Outline of Psychology" (NATURE, December 10, 1896), Mr. W. E. Johnson points out what he takes to be a fallacy underlying the calculation of the number of possible sensation qualities in that and other text-books. I believe with Mr. Johnson that the qualitative series is in many cases (not all: *cf.* taste, *e.g.*) continuous. But I do not think that this makes the calculation of distinguishable qualities fallacious.

Mr. Johnson's argument is briefly as follows :—Let A B C D be stimuli of the same physical continuum (*e.g.*, wave-lengths), whose values are such that the sense qualities corresponding to A and D are just noticeably different. Then we have :—

Stimulus	...	...	...	A	B	C	D
Sensation	...	...	...	*a*	[*b*]	[*c*]	*d*;

and the syllogism runs :—

a is not *d*,
b is *d*,
∴ *a* is not *b*.

But by hypothesis, *a* is *b*, being indistinguishable from it. Hence to make difference = distinguishableness in calculation leads to a logical fallacy.

If now it were a case of diversity in logical predicate *vs.* identity in experience, the psychologist would be found to decide in favour of experience. But I think that the whole syllogism is erroneous. As a matter of fact, going from left to right, we have the series :—

Stimulus	...	...	..	A	B	C	D
Sensation	...	...	...	*a*	*a*	*a*	*d*

and, going from right to left, the series :

Stimulus	...	...	...	A	B	C	D
Sensation	...	...	...	*a*	*d*	*d*	*d*

from which the only conclusions are :—

Some *a* is not *d*,
Some *a* is *d*, . . .

i.e., two particular propositions. It is of the very essence of the just noticeable difference that it is cognised under certain conditions, and not under all.

So far, then, the fallacy turns out to be imaginary. There are no sensations *b* and *c*, qualitatively distinct from *a* or *d*. Nor can there be, whatever value of stimulus be taken as starting-point for the determination. An observer working with stimuli B C D E . . . would get the sensation series *b e i m* . . . which would be qualitatively indistinguishable from the series *a d h l* . . .

Calculation of qualities by arithmetical progression presupposes, of course, a constancy (found as in tones, or calculated as in colours) of the *absolute* difference limen. Weber's law holds only of sensation intensities, which I expressly decline to calculate (p. 70). There is one qualitative series in which a uniformity resembling Weber's law obtains: the black-white series. But this series is in many respects anomalous, its qualities seeming to have the function of visual intensity; and neither its physiology nor its psychology is at present very satisfactory. (For the calculation of the number of brightness qualities, see Prof. König's paper, Ebbinghaus' *Zeitschrift*, vol. viii. pp. 377 ff.)

(2) Mr. Johnson further objects to my analysis of the process

of comparison. If I had said only what he quotes me as saying, his criticism would have been justified. As it is, I say (in the same context):—

"Verbal association and judgment are, in themselves, comparatively simple processes; but when the word associated or predicated is a fully formed concept, we realise that the simplicity of form is deceptive, that much mental elaboration lies behind."

"Likeness" and "difference" are concepts, and have conceptual significance. I devote a section to the formation of concepts in general (pp. 294 ff.). It is not, however, the duty of Psychology, but of Anthropological Psychology, to show the genesis of particular concepts (pp. 292, 300). I was concerned simply with the process of comparison as introspection reveals it in the adult mind, not with its logical or genetic aspects.

E. B. TITCHENER.

(1) As regards the difficulty involved in counting sensation qualities, the point of difference between Prof. Titchener and myself is subtle, but philosophically interesting. I think we may both admit that the question cannot be settled by considerations of purely formal logic. In fact, Prof. Titchener's two premisses logically lead to the conclusion that "One sensation *a is not the same as* another sensation *a*, although the two are, *ex hypothesi*, indistinguishable." The question between us is as to the interpretation of the relation "not the same as" in this connection. My contention is that the *one* and the *other* sensation differ—not merely numerically or extrinsically—but qualitatively or intrinsically. Since the one sensation *a* is distinguishable from *d*, and the other sensation *a* is not distinguishable from *d*, it seems to me that this difference between them cannot be referred to merely extrinsic conditions, but must depend on a sensationally qualitative difference in the sensation-qualities themselves.

(2) If I have unintentionally misrepresented Prof. Titchener's views on the process of comparison, I should be glad to take this opportunity of making amendment by quoting a passage from p. 299, which seems to me sound:—"In every association two ideas are brought into connection. When the connection itself has become the object of attention, when, *i.e.* we have formed an idea of connection, as distinct from the ideas which are connected, we speak of it as a *relation*." If this passage is applied to the relation of likeness or difference apprehended in the process of comparison, I have no ground of dispute with Prof. Titchener. Only in this case I fail to see how any significance or importance can be attached to the phrase "verbal association" employed in describing the process of comparison.

W. E. JOHNSON.

Durham Degrees in Science.

AMONG the official notices of the University of Durham, I find it recorded that, on Tuesday, December 15, six gentlemen received the degree of Master in Science *by vote of Convocation*.

The degree of Master in Science has in the past been purely a *merit* degree. It was conferred only upon those who had previously taken the degree of Bachelor in Science, who were of, at least, two years' standing, and who succeeded in passing an additional examination in some branch of one of the scientific subjects professed at the University. The degree was, in fact, until to-day, an authoritative statement that the holder was not only a specialist in his particular subject, but also that he had received that sound University training in science and general knowledge of which the Bachelor in Science degree is a proof.

This has now been changed. The degree has been granted merely "by vote of Convocation" for no specified cause. Before December 15, it was evidence of merit of a particular kind. Now it is not. Apart from other considerations, this is a great hardship upon many other graduates in science. Grouped together in the list of Masters in Science are those who have gained the honour by their scientific attainments, and those who have received it for non-specified reasons by vote of Convocation.

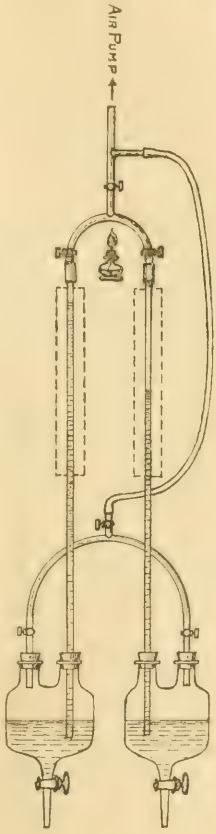
Such a radical change in the nature of a degree deserves public notice, and this must be my apology for troubling you with this letter. X.

January 1897.

NOTE ON METHOD SUGGESTED FOR MEASURING VAPOUR PRESSURES.[1]

THE distillation of vapour from one of the vertical tubes to the other, referred to at the end of Operation No. 4, in my communication published in last week's NATURE (p. 373), may be wholly got quit of by the following simplified mode of procedure.

Operate first on one only of the liquids until it is got into equilibrium, with its upper level at any convenient marked point in its glass tube, and nothing but its own



vapour between this surface and the closed stopcock immediately above it; the upper-neck stopcock over the bottle for this liquid being also closed.

Operate similarly on the other liquid; and close both the air-pump stopcocks, so that now we have all the stopcocks closed.

Open now very gradually the upper-neck stopcocks of the two bottles. While doing so, prevent the liquid from rising in either tube above the marked point by working the air-pump and very slightly opening the lower air-pump stopcock. When both the upper-neck

[1] See NATURE, p. 274.

stopcocks are wide open, any adjustment that is considered desirable for the level of the liquid standing higher than the other in its glass tube, may be deliberately made by drawing out or letting in a little air through the lower air-pump stopcock.

Either or both liquids may be thoroughly stirred at any time to ensure homogeneousness by alternately exhausting and letting in air to the bottle or bottles by means of the air-pump and the lower air-pump stopcock, the upper three stopcocks being kept closed.

Operation No. 6 of my article on the subject, in last week's NATURE (p. 274), must be performed as often as is found necessary. Every one of the stopcocks must be kept closed except when it is open for operation or observation.

The metal tube connecting the upper necks of the two bottles must be long enough, or of fine enough bore, to prevent diffusion of vapour to any sensible extent from either bottle to the other during the time of an observation. It ought to be kept at a temperature somewhat higher than that of the bottles, to prevent any liquid from condensing as dew on its inner surface. KELVIN.

Glasgow, January 23.

THE GRAVITATION CONSTANT AND THE MEAN DENSITY OF THE EARTH.

IN the year 1884, Prof. Dr. Franz Richarz and Dr. Otto Krigar-Menzel commenced a series of experiments having for their object an accurate determination of the values for the constant of gravitation and the earth's mean density. The work divided itself naturally into two parts, and the results of the first series of weighings were communicated to the Berlin Academy of Sciences in March 1893. Since that time the second series has been concluded, and the main results of the whole investigation are summed up briefly in the same society's *Sitzungsberichte* for November 1896, the authors leaving the publication of the full account, containing the details of the measurements, for a future period.

The instrument with which the measurements were made was a kind of double-balance having two pans on each side of the beam, one above the other, connected in the vertical direction by a thin rod 226 centimetres long. The point of this arrangement was that the acceleration due to gravity on the two lower pans was greater than that on the upper one, in consequence of the difference of level. The first day's weighing consisted in determining the difference in weight of two practically equal spheres, one being placed in the upper pan on one side of the arm of the balance, and the other in the lower pan on the opposite side. Gauss' system of double weighing was employed throughout, the masses being changed from one side to the other. The measured difference was therefore due to two sources—to the inequality of the masses weighed, and to the difference of the force of gravity. The procedure for the second day was to change the positions of the masses being weighed; this consisted in placing the sphere that was in the upper pan in the lower one on the same side of the arm, and in putting that on the other side of the beam in the upper pan: a second series of weighings was then made. Such a series of measurements as these was included in the work recorded in the first publication. It was found that the measured difference was not the same on the two days, for although the difference in weight of the masses always remained the same, the difference in the value of gravity, due to the virtual displacement of the masses, altered its sign. By subtracting these differences for each day's work, the mass-difference was entirely eliminated, and there only remained that between the two values of gravity due to the two heights of the scale-pan.

In the second part of the work, for obtaining the mean density of the earth, a large cubic block of lead, having a mass of 100,000 kilograms, was used. This was supported firmly on massive pillars under the upper and above the lower scale-pans, the connecting-rods of the latter passing through holes in the block. The presence of this great attracting mass had the effect of apparently increasing and decreasing the value of gravity acting on the spheres in the pans according to their position—that is, according as they were in an upper or a lower pan. In the system of arrangement adopted—namely, that of placing the spheres in an upper and lower pan on opposite sides of the fulcrum—the acceleration of gravity in the upward direction was lessened by double the amount of the attraction of this great mass of lead. By connecting to two days' weighings, instead of double the diminution of the value of gravity with the height, the result was lessened by four times the attraction of the block of lead. A combination of the results obtained, both with and without the leaden cube, gave the fourfold attraction of the leaden cube free from the variations of gravity.

Very elaborate precautions were taken to eliminate effects of air currents, changes of temperature, &c., and these seem to have been fairly overcome both practically and theoretically. It is also needless to state that the number of weighings made was very considerable.

The value thus finally deduced for the constant of gravitation was

$$G = (6{\cdot}685 \pm 0{\cdot}011)10^{-8}\ \frac{\text{cm.}^3}{\text{gr. sec.}^2}$$

Using this value, the mean density of the earth obtained was as follows:—

$$\Delta = (5{\cdot}505 \pm 0{\cdot}009)\ \frac{\text{gr.}}{\text{cm.}^3}$$

This value, as will be seen from a perusal of the following table, falls between those found by Poynting and Boys:—

Observer.	Method.	Mean density of earth.
Cavendish	Torsion balance ...	5·45
Reich	,,	5·49 and 5·58
Baily	,,	5·67
Cornu and Baille ...	,,	5·56 and 5·50
Ph. von Jolly	Long-arm balance ...	5·692
J. Wilsing	Pendulum apparatus	5·594
The same with elimination of known sources of error	,,	5·577
J. H. Poynting	Balance	5·4934
C. V. Boys	Improved torsion balance ...	5·5270
Richarz and Krigar-Menzel	Double balance ...	5·505

TUBES FOR THE PRODUCTION OF RÖNTGEN RAYS.

MANY and various are the forms of the bulbs and tubes employed for the production of Röntgen rays, as may be seen from the designs that are represented in the accompanying illustration from *La Nature*. Different experimenters favour different tubes, and believe that the forms they use possess advantages over all others. Up to the present, however, it may be said that three processes are utilised in the production of Röntgen rays. There is (1) the old form of Crookes' tube, in which the kathode rays impinge directly upon the glass or screen in front of the kathode; (2) the form of tube in which the kathode rays fall upon, and are reflected by the anode; and (3) the tubes in which both direct and reflected rays are utilised. In the accompanying illustration, the first

method is exemplified by Nos. 1, 2, 3, 4, 6, 7, 10, 11, 12, 13, 14, 17, 18, 20, 21, 24, 26, 28, 32; the second system, by the adoption of which instantaneous Röntgen photography became possible, is adopted in the tubes numbered 5, 8, 9, 15, 16, 23, 25, 27, 29, 30; and the third principle is illustrated by Nos. 19, 22, 31. The Crookes' tube, represented by No. 1, is very well known, and is still used for Röntgen photography on the continent. No. 2 represents a form of tube used when the movement of the kathode stream by a magnet is desired, so that the rays can be made to impinge upon different parts of the glass. In No. 3, the concave kathode is brought very near to the glass, so that its focus is really outside. No. 4 shows a tube with a kathode which can be revolved in a plane at right angles to its own face. No. 5 has two kathodes, and the rays from them are reflected from a platinum anode. In No. 6 the anode is formed of an aluminium disc, which is traversed by the kathode rays; but the advantages of this form are not very clear. Two kathode streams are utilised in No. 7. The form of tube which workers in this country find gives the best results, is represented in No. 8, and is known as the "focus" tube, or tube of Jackson pattern. In this the kathode rays fall upon, and are reflected by, a platinum mirror which forms the anode. No. 9 has two anodes, one of them a hollow platinum cone which reflects the kathode rays. The tube shown in No. 10 is especially suitable for use with currents of high frequency; it is uni-polar, and has an external anode. No. 11 has pointed poles, either of which may be the kathode. The tube No. 12 has a platinum kathode, covered on its convex side by a glass insulator so as to reduce the loss of radiation. No. 13 is found to give good effects on fluorescent screens. No. 14 is for use with currents of high frequency, and has only one pole in the tube. No. 15 is a useful form of tube, one of its advantages being that two photographs can be taken at the same time by the reflection of the rays from the kathode on either side. In the tube represented by No. 16, a circular disc forms the kathode, and at its centre is set a hollow cone of platinum as an anode. No. 17 represents a form of tube for the investigation of the action of kathode rays upon a substance. The end of the cylinder is made so that substances can be introduced into the tube. Another kathodic cylinder is shown in No. 18; the kathode is situated at the place usually occupied by the anode, the latter pole being at the top. No. 19 combines the actions of both the direct and reflected rays. The kathode passes through a concave anode of platinum, and all the rays emitted by it are utilised either directly or after reflection. A cylinder employed at the commencement of work with kathode rays is shown in No. 20; a good point about it is that the poles are some distance apart, so there is little fear of sparking outside the tube. A cylinder with an interchangeable window opposite the kathode is represented in No. 21. A tube with two anodes (No. 22) is designed on the principle of the reflection of the kathode rays, the kathode being placed centrally inside a reflecting anode. Another bi-anodic form is the large bulb shown in No. 23. The next figure (No. 24) has slips of aluminium as poles, and either of them may form the kathode. No. 25 is constructed so that the platinum cone which forms the anode, reflects the rays from four kathodes placed around a circumference, and kept in action by as many coils. A tube, useful for showing the place of origin of active rays, is shown in No. 26. The next (No. 27) has two anodes and two kathodes; the two kathode streams are reflected from the anodes, and, meeting one another, are given additional power. No. 28 resembles No. 10, but it has the defect that it rapidly becomes heated. In No. 29 the kathode is formed of an annular aluminium plate, the rays from which strike upon the central platinum cone and are concentrated to a point by reflection. No. 30 is designed to show the effect of the reflection of kathode rays in a space as small as possible. The tube has an electrode of palladium. The tube No. 31 is very good for use with fluorescent screens, the kathode rays being reflected from a large anodic surface, with the result that the phosphorescent area of the glass is exceptionally great. The tube shown in No. 32 represents the first form used by Prof. Röntgen.

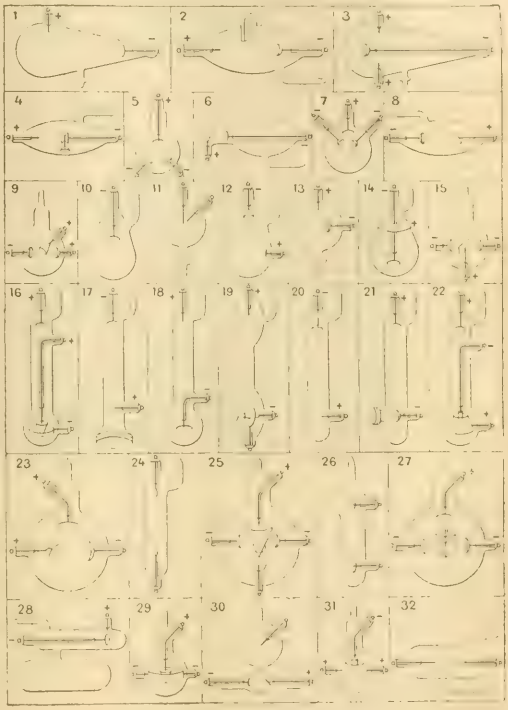


FIG. 1.—Forms of tube used for the production of kathode and X-rays. 1, 2, Crookes' tube; 3, Séguy tube; 4, Wood tube; 5, Séguy tube; 6, Chabaud and Hurmuzescu tube; 7, Séguy tube; 8, "Focus" tube; 9, Séguy tube; 10, d'Arsonval tube; 11, Séguy tube; 12, Puluj tube; 13, Séguy tube; 14, d'Arsonval tube; 15, Le Roux tube; 16, 17, 18, Séguy tubes; 19, Rufz tube; 20, Crookes' tube; 21, 22, 23, Séguy tubes; 24, Röntgen tube; 25, Brunet-Séguy tube; 26, 27, Le Roux tubes; 28, Colardeau tube; 29, Séguy tube; 30, Colardeau tube; 31, Séguy tube; 32, Röntgen tube.

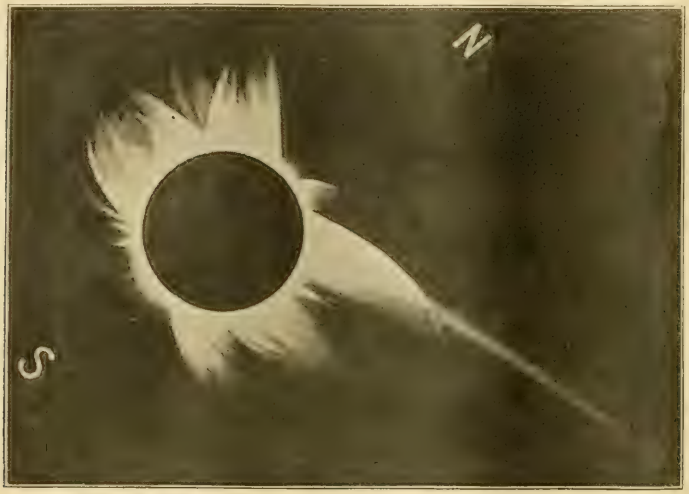
RUSSIAN OBSERVATIONS OF THE CORONA OF AUGUST 9, 1896.

I HAVE for many years been a reader of your honourable and interesting journal of science, NATURE. I beg you to accept for it the accompanying picture of the solar corona, as I had the opportunity to see it on August 9, 1896, in Sii-Kavuopio (on the Upper Muanio, in Lappania), where I went last summer as a member of the Lappanian Solar Eclipse Expedition of the Russian Astronomical Society.



This photograph is the reproduction of a drawing carefully made by myself on the same scale for the Astronomical Society, and in which I tried to combine all the details of ten corona-photographs, which our expedition were successful in obtaining, the instruments used being—

A 7-inch refractor (object-glass "Merz").
A 4-inch camera (object-glass "Ross").
A 2-inch camera (object-glass "Steinheil").

Combined with the pictures obtained by these is the general impression of the corona, as seen with the eyes, during fine and calm weather and very transparent air.

NICOLAS KAULBARS,
Lieutenant-General, and Chief of Staff of the Finland Military District.

NOTES.

AT the last meeting of the Chemical Society it was announced that Mr. J. J. Tustin had made a donation of one thousand guineas to the Research Fund of the Society.

M. FILHOL has been elected a member of the Section of Anatomy and Zoology of the Paris Academy of Sciences, in succession to the late M. Sappey.

THE Paris Academy of Sciences has been invited to send representatives to the International Congress of Naval Engineers and Architects, to be held in London next July. Efforts are being made to ensure that the forthcoming meeting in London shall be as brilliant and generous in hospitality as the last one held in Paris.

THE German Emperor is always ready to recognise deserving work in science. He has just conferred the Order of the Crown on Dr. Hauchecorne, the Director of the Prussian Geological Survey and of the Berlin School of Mines, and the Order of the Red Eagle on Dr. Hampe, the eminent Professor of Chemistry at the Clausthal School of Mines, and on Dr. Loretz, of the Prussian Geological Survey.

PROF. CHARLES D. WALCOTT, Director of the United States Geological Survey, reports to the Secretary of the Interior the existence of an enormous gold belt in Alaska. An expedition sent out by the Survey in May last, investigated the valley of the Yukon River, from the British boundary to the mouth of the river. All the well-known placer deposits were examined, and the origin of the gold in them was found to be the quartz veins along the head-waters of the various streams entering the Yukon. The length of the gold belt in Alaska is 300 miles, entering that territory near the mouth of Forty-Mile Creek, and extending westward along the Yukon valley at the Ramparts.

M. FAYE, whose contributions to astronomy and meteorology are of world-wide renown, was elected a Member of the Paris Academy of Sciences in January, 1847. In honour of his jubilee, at the meeting of the Academy on Monday, M. Chatin, the new President, delivered an eloquent tribute to a life devoted to the advancement of science, and enumerated his most notable achievements. At the close he presented M. Faye with a gold medal representing the astronomer's effigy surrounded by an inscription affirming the pride of his colleagues in his friendship, and their admiration for his work. We learn from the *Times* that at a dinner at the Grand Hotel on Monday evening, presided over by M. Jannsen, M. Faye received from General Billot, Minister of War, the insignia of the Grand Cross of the Legion of Honour, bestowed upon him by special decree of the President of the Republic. M. Rambaud, Minister of Education, was also present, and among those who spoke were M. Loewy, Director of the Paris Observatory, and General Toulza, of the École

Polytechnique. M. Faye's numerous friends and pupils at this school offered him a group in bronze. M. Faye was the favourite pupil of Arago, and is now eighty-three years of age.

IN connection with the International Committee of Aeronautics, the second ascent of sounding balloons will take place on Monday next, February 1, at 11 a.m., local time, at each station participating in the work. The balloons are fitted with instruments for registering temperature and altitude, and have an ascending force more than five times greater than that due to the total weight. Any one who should happen to witness the descent of one of the balloons should carefully look after the records, and send them to the office of the *Aerophile*, 14 rue des grands Carrières, Paris.

IT will be of interest to botanists and zoologists throughout the world, to learn that a biological survey of Alabama has been organised and put into operation. The survey will be carried on under the auspices of the Alabama Polytechnic Institute, and will be manned by the specialists engaged at that institution in the various lines of biological investigation. It will have for its object the study, in field and laboratory, of all plants and animals occurring in the State, and of the various conditions affecting them. The work will be done systematically and thoroughly, and all the results published. In a region so interesting and little worked as this portion of the Southern United States, careful and extended research will be sure to yield results of the greatest value. Large quantities of material in all groups of plants, and of animals (especially insects) will be collected and properly prepared. In connection with the survey there has been founded an Exchange Bureau, from which will be distributed all duplicate material. Any one desiring to correspond relative to specimens, literature, or the work of the survey, should address, "Alabama Biological Survey, Auburn, Alabama."

AT the General Horticultural Exhibition to be held in Hamburg from May to September in the present year, there will be a scientific department, managed by a committee, of which Dr. Zacharias and Dr. Klebahn are members. Exhibitions are invited and prizes offered in the following special subjects: (1) Diseases of cultivated plants produced by mechanical causes, or by conditions of atmosphere or soil; (2) animal and vegetable enemies of horticulture and fruit-growing; (3) animal and vegetable friends of horticulture; (4) abnormalities and sports; (5) comparative experiments on manures; (6) wild ancestral forms of cultivated plants; (7) living exotic useful plants in pots; (8) collections of the most important exotic useful plants (dried specimens), or of preparations from them; (9) collections of plants, or parts of plants, from morphological or biological points of view; (10) results of scientific experiments on pollination; (11) scientific aid to horticulture—implements, tables, models, &c. Information of intended exhibits should be sent to the Director of the Botanic Garden, Hamburg, before March 1.

MM. CORNU has been elected President of the Botanical Society of France for the current year.

THE Annual Meeting of the German Botanical Association will be held this year in Frankfurt-a-Main, commencing on September 22.

A BOTANICAL MUSEUM has been established at Weimar, at the sole cost of Prof. Haussknecht. It is designed to be "a Central Institution for investigations in systematic botany," and will be under the control of the Thuringian Botanical Union.

A VIOLENT earthquake is reported to have occurred in the district of Delvino, in Epirus. Several villages are stated to have been destroyed, and it is feared that there has been serious loss of life.

THE death is announced of Mr. T. Gwyn Elger, well known by his numerous contributions to selenography, both in the form of drawings and notes of the principal features of the lunar surface. Mr. Elger became a Fellow of the Royal Astronomical Society in 1871, and was in his sixtieth year at the time of his death.

WE notice with regret the announcement of the death of Dr. Edward Ballard, author of many papers and works on medical and scientific subjects. Dr. Ballard was elected a Fellow of the Royal Society in 1889. He was eminently distinguished as an investigator of causes of disease, and as a promoter of scientific sanitary administration. Among numerous other works, he published a valuable paper "On the influence of weather and season on public health, based on the statistical study of 272,000 cases of sickness (1857–68)." He was also the author of many important reports to the Local Government Board on particular outbreaks of disease, local, or more or less general.

TOWARDS the end of last year, George Daniel Eduard Weyer, the Professor of Mathematics and Astronomy at the Kiel University, passed away. Prof. Weyer was a great favourite among the students, and was as well known among the officers of the Merchant Service of Germany as he was among those of the Royal Navy. On account of his astronomical calling, he was familiarly known as "alte Seni," and every one loved him—from Admiral to Lieutenant—for nearly all of them had been his pupils at some time or other, and this was how they expressed their familiarity for their old teacher. A brief summary of the positions Prof. Weyer held during his lifetime will serve, perhaps, to show how he eventually became so closely connected with the Navy. Born at Hamburg in the year 1818, he spent four years (1839–43) at the Hamburg Observatory. For the next two years he studied astronomy and mathematics in Berlin. From 1847–50 he was assistant at the Hamburg Observatory, and teacher at the School of Navigation in connection with the observatory. When the School for Naval Cadets was established in Kiel, Weyer accepted a position there. In 1852 he was a "Privatdocent" at the University, and was made "Ordentliche" Professor in 1865. His connection with the Navy may be said to have now begun. In 1864 he was the Examiner in Navigation for the Prussian Navy, and lectured for more than twenty years at the Marine-Akademie in Kiel. Weyer was the author of many works, most of which related to nautical astronomy, and his aim throughout was directed to the improvement of the methods of determination of position at sea. His death will be felt by all his friends and pupils, for he was widely known, and last, but not least, by nautical science, which loses a faithful student.

> "Mein Sohn, nichts in der Welt ist unbedeutend,
> Das erste aber und Hauptsächlichste
> Beim allem ird'schen Ding ist Ort und Stunde."
> (Seni in *Wallenstein's Tod*, I. Part.)

FOR the last month (says the *Times*) the Colonial Office, the Natal and Cape Governments, and the Board of Agriculture have been in communication as to the best means of preventing the cattle plague in South Africa from spreading into either Natal or the Cape Colony. Various inquiries have been made as to what steps should be taken, and on Thursday last, at the Board of Agriculture, a special conference of heads of departments concerned was held to consult together on the subject. The chief officials concerned of the Board of Agriculture and the Colonial Office met the Agents-General of Natal and the Cape Colony and other Cape authorities. Further meetings will be held on the subject, and it is contemplated that the Government will sanction every effort to save the colonies of Natal and the Cape from rinderpest.

SINCE the plague was officially recognised in the Bombay mortality returns on September 26, and despite the decrease in

the population, 9835 deaths have occurred in excess of the average for the last five years. These are attributed by the *Times of India* to the plague. Continental Governments are showing great activity in regard to precautionary measures. The Austrian Academy of Science has decided to despatch three medical men to Bombay to study the circumstances connected with the prevailing epidemic. A special sanitary mission, sent by the Medical Board and accompanied by the French delegate, has left Suez for the quarantine stations on the coast of the Sinai Peninsula, in order to determine what measures are necessary to assure the immunity of Egypt from contagion. The *Times* correspondent at St. Petersburg states that the Russian newspapers continue to complain of the British Government for delaying to take measures against the spread of the plague. To secure the safety of Russia's Asiatic possessions, the Minister of the Interior has issued instructions for the opening of fourteen stations of medical observation along the land frontiers of Persia, Afghanistan, and Chinese Kashgar. A special commission has been appointed by the Tsar to take measures for the prevention of the importation of the plague into Russia. Practically all the European Governments have appointed representatives for the Sanitary Conference to be held at Venice on February 10.

THE weather has continued very wintry during the past week, sharp frost occurring at night over the entire kingdom, and snow has fallen on most days over a large part of the country. A heavy north-easterly gale occurred on Friday and Saturday, the storm, coupled with the high sea which was running, doing much damage on our east coasts. The gale was accompanied by a heavy fall of snow, deep drifts being formed in the midland, southern, and eastern districts of England, and occasioning much inconvenience and delay to the ordinary traffic. In places trains were blocked, and some few deaths have occurred owing to the severity of the weather. There was a temporary give in the frost on Monday, owing to the arrival over the northern part of our islands of a cyclonic storm area from the Atlantic. There was a renewal of the gales on our coasts, and snow fell again in many places. In London a heavy snow squall occurred at about five o'clock on Monday afternoon, and was accompanied by thunder and lightning. The frost was very sharp again on Tuesday and Wednesday, but the changes of temperature continue very fitful.

THE worked flints obtained by Mr. W. J. Lewis Abbott from the Cromer Forest-Bed are described by him in the February number of *Natural Science*. For the benefit of those not familiar with the geology of the Cromer district, it is pointed out that the valley to the west of Cromer, towards Sherringham, is still cloaked with a palæolithic gravel, below which come the fantastically-twisted and folded glacial beds, termed the contorted drift, and under this occurs the Forest Bed series. This series is, however, not a Forest-Bed at all, but was deposited in the estuary of a river. The flints obtained by Mr. Abbott have every appearance of having been fashioned by man. The conclusion arrived at is: "Bearing past history in mind, and the reception which has been accorded to these specimens, the unquestionable evidences they offer of being artificially worked, the unmistakable positions from which they were obtained, and the conditions under which some of them were found in the matrix, are we not justified in admitting the existence of man in Britain in the Forest Bed period?"

MR. J. LL. WILLIAMS has a very curious note in the number of the *Journal of Botany* for January, on the drunken habits of certain humble-bees. The intoxicant is the honey produced by the crowded flowers of the capitulate heads of certain Compositæ (*Carduus nutans* and *lanceolatus*, and *Centaurea scabiosa*), and Dipsacaceæ (*Scabiosa Succisa*). The intoxication is indicated by rolling on the back, striking the legs wildly in the air, and general helplessness. The bees rapidly recovered from the effects, and, in most cases, were eager to repeat the debauch; but one individual, which had been shut up in a vasculum with copious supplies of *Centaurea Scabiosa*, manifested, the next morning, a praiseworthy remorse and disgust, "raising its head and fore-legs as high as it could above the plants, then precipitately hurrying away as soon as released." The most dissolute species appears to be the neuter of *Bombus lapidarius*. The author suggests that this may in time become a normal mode of cross-pollinating the flowers in question.

SOME interesting experiments by Prof. Felix Plateau, of Ghent (*Bulletin de l'Académie Royale de Belgique*), tend to disprove the view, so often advanced, that the brightly coloured petals of flowers are necessary to attract insects. The method of observation adopted—viz. by removing the corolla and watching whether insects continue to visit the flower—had previously led to contradictory results in the hands of different observers, including Charles Darwin. These discrepancies the author attributes to want of care in removing the petals; care must, indeed, be taken to avoid handling the flowers, or doing anything which might influence an insect's sense of smell. Prof. Plateau removed the brightly coloured corollas from the flowers of *Lobelia Erinus*, *Œnothera biennis*, *Ipomœa purpurea*, *Delphinium Ajacis*, *Digitalis purpurea*, and *Antirrhinum majus*, and the blue barren florets from the capitulum of *Centaurea cyanus*. In every case, except that of *Antirrhinum majus*, the mutilated flowers were observed to be freely visited by various kinds of insects (bees, bumble-bees, flies of the *Syrphidæ* family, and an occasional butterfly), no special preference being exhibited for flowers that were left intact. The insects not only sucked honey from the mutilated flowers, but they often circled round them without alighting. In the case of the snapdragon, several bumble-bees hovered round the mutilated heads, but subsequently left them for those with entire flowers, a result explained by the peculiar mode in which bees have to enter the corolla, which would render the absence of that organ perplexing to them. Finally, Prof. Plateau covered several of the large umbels of *Heracleum Fischèrii* with rhubarb leaves, and it was found that even when thus masked they were freely visited by insects. These results suggest that insects are guided to flowers largely by their sense of smell.

IN the same publication, M. Victor Willem describes experiments showing that the variations observed by Semper and Varigny, in the development of fresh-water mollusca (*Limnæa*, *Planorbis*), are attributable to the greater or lesser aëration of the water in which they grow, those specimens which are reared with free access of air developing to the largest size.

PROF. D. MAZZOTTO has completed a determination of the index of refraction of water for electric waves of length varying from two metres down to twenty-five centimetres. The experiments, which are described in the *Atti dei Lincei*, show that between these limits the index is constant and equal to 9·00 at 19°, thus agreeing well with the theoretical value (8·85) obtained by taking the square root of the dielectric constant.

IN a part of the *Proceedings* of the Biological Society of Washington, just issued, Dr. C. H. Merriam describes a very remarkable small, short-eared, tailless rabbit, which has recently been discovered on Mount Popocatepetl, in Mexico, at the height of about 10,000 feet. This singular animal, which, instead of moving by leaps, like an ordinary rabbit, runs about on all-fours, in the grass of the mountain, has been named by Dr. Merriam *Romerolagus Nelsoni*. The clavicles in this new form are complete, and not imperfect as is usual in the family *Leporidæ*.

THE mammals collected by Dr. Donaldson Smith, during his recent expedition to Lake Rudolf, have just been described at Philadelphia by Mr. S. N. Rhoads. The collection contained representatives of fifty genera and seventy-seven species, seven of which are now characterised as new. These are mostly rodents. Perhaps the most noticeable discovery is that of a second species of the very peculiar African genus *Lophiomys*, which Mr. Rhoads proposes to call *Lophiomys Smithi*. Dr. Donaldson Smith also obtained a specimen of the curious hairless mole-rat, *Heterocephalus glaber*, of which only two examples had been previously captured.

MR. FREDERIC W. TRUE, the Curator of the Department of Mammals in the U.S. National Museum, has just completed and published an excellent review of the Moles of North America, based principally on the large series of specimens of these insectivorus mammals under his charge. He recognises two sub-families of Moles as occurring in the Nearctic Region, *Talpinæ*, with four genera, and *Mygalinæ*, with one genus. Special attention is paid to the distribution of these animals in America, which presents several interesting features. Two of the five genera of Moles are strictly confined to the Pacific Coast, while the three remaining genera are only met with east of the Rocky Mountains. The most remarkable form, perhaps, of the American Moles is the so-called Star-nosed Mole (*Condylura cristata*), which carries an enlarged fleshy disc at the extremity of its snout, obviously for use as a highly developed tactile organ.

THE insects which affect the cotton plant in the United States are described by Mr. L. O. Howard in *Bulletin* No. 33, published by the U. S. Department of Agriculture. The cultivation of cotton in the United States has gone through a curious change with regard to the depredations of insects. Not very long ago, the average annual loss to the cotton-growers from the work of a single species of insect amounted to 15,000,000 dols. This insect was the so-called cotton caterpillar, or cotton-leaf worm (the larva of *Aletia argillacea*, Hübn.). Down to the year 1881 the damage done by this insect so far exceeded that inflicted by any other species that other forms had received but little consideration. Since about 1880, however, the cotton-worm has ceased to be a serious enemy to cotton. It is undoubtedly much less abundant and destructive than it was fifteen years ago, and no longer holds the first position among the insect enemies of the cotton crop. The so-called bollworm (the larva of *Heliothis armiger*, Hübn.), which a few years ago did much lesss damage than the cotton-leaf worm, now ranks as the most prominent enemy. It is curious to note this decline of one harmful insect and rise of another. Students of biology will remember many similar instances.

THE uncertainty which still exists as to the ultimate causes of volcanic outbursts is illustrated by two papers which appear, at no great distance apart, in the *Proceedings* of the Boston Society of Natural History for 1896. The author of each paper starts out with the consideration of certain phenomena occurring on a small scale, and eventually applies his conclusions to the problem of the distribution of volcanoes; but both start and conclusion are widely separate in the two cases. Mr. N. S. Shaler begins with the escape of gases from a viscous liquid, and noting how, once a path is opened up, a regular procession of bubbles follows along it, applies this first to explain the vertical jets of water and gas that issued from the ground at the Charleston earthquake, and then to the repetition of volcanic eruptions at the same locality. He suggests that it is the water included in deposited sediments which becomes the explosive steam of a volcanic outburst, and regards rapidity of sedimentation and the conductivity of the earth's crust as correlated factors in the establishment of volcanic action in any region of the earth's surface. Mr. J. B. Woodworth, on the other hand, deals with the details of fracture under strain, and his paper is illustrated with some very beautiful photo-reproductions of the fracture-surfaces of fine-grained homogeneous rocks. He compares the distribution of volcanos (particularly in the Sandwich Islands and western coast of the Pacific) with the distribution of fracture-lines at the margin of a joint surface. Whether this comparison be justified by further study or not, the paper is a most valuable addition to the literature of fracture-structures.

AN interesting note on the Australian Snow Country has been received from Mr. John Plummer, of Sydney. A railway journey of only thirteen hours separates Sydney from the threshold of a region of ice and snow, where, even during the hottest days of the Australian summer, fires and blankets are necessary, while residents on the interior plains are suffering from the sweltering heat. Mount Kosciusko, the highest peak in Australia, being 7171 feet above sea-level, is in that cool region. It forms part of the Muniong Range, the northernmost portion of the Australian Alps, which extend across the upper waters of the Murray into Victoria, the whole of the surrounding country being more or less mountainous. The hills of the Muniong Range are popularly known as the Snowy Mountains, portions of their summits being above the line of perpetual snow. There is no Alpine climbing to be done in scaling Mount Kosciusko. The ascent begins in reality twenty-five miles away from the summit, and the slope is so gradual that it may be performed without fatigue by any one in ordinary health. Highest Australian mountain though it is, the visitor can drive to the top of it. There are no trees within some miles of the mountain top; but gigantic mosses grow there, and beautiful wild flowers. Loveliest of all, perhaps, are the mountain snowdrop and the elychrisan, or everlasting flower, which in this district has a black centre instead of the more common yellow one. Another interesting feature of the locality is the number of small lakes formed by the melting of the snow in basins between the hills. The highest of these lakes—it is the highest sheet of water in Australia—is situated about 300 feet from the summit of Mount Kosciusko.

ALTHOUGH milk has so frequently been held responsible for the dissemination of diphtheria, yet curiously but few exact investigations have been made on the behaviour of diphtheria bacilli in milk. Hesse found that cholera bacilli underwent deterioration in raw milk; that, in fact, when kept in these surroundings at a temperature of 37° C., they were entirely destroyed within 22 hours. Caro of Naples, on the other hand, working with anthrax bacilli in raw milk, states that these microbes flourish abundantly in milk, and abate no jot of their virulence under these conditions. Prof. Schottelius has repeated these experiments, and has entirely confirmed them; he has, however, extended his investigations to the behaviour of diphtheria bacilli in milk. In a recent number of the *Centralblatt für Bakteriologie*, Part i., a summarised account is given of these researches, and it appears that in fresh milk diphtheria bacilli find an exceptionally satisfactory material for growth and multiplication. In sterilised milk, however, their growth was not so abundant, and was less strongly marked than in the ordinary broth used for cultivation purposes. As the milk was only sterilised for half an hour by means of the ordinary Soxhlet apparatus, this difference in the vitality of the diphtheria bacilli in the raw and heated milk, respectively, could not have been due to the milk having become acid through heating. Hesse has shown that when milk is subjected to prolonged sterilisation at a high temperature it exhibits an acid reaction. Prof. Schottelius concludes his paper with a warning, now so often

repeated, of the danger attending the consumption of milk in its raw unsterilised condition.

THE origin and evolution of human marriage is a subject that appeals to many minds, and much has been written upon it by more or less competent students. In *The American Anthropologist* for November 1896, W. J. McGee deals with some marriage observances of a few American aboriginal tribes. He traces an instructive sequence, beginning with the Seri Indians, who are probably the most primitive people in North America, and about whom very little has previously been published. Amongst these peoples the man is a suitor, not so much from personal inclination as from tribal incentive; individual caprice is subordinated to the welfare of the community, and the matter is regulated by his female relatives and the maiden's mother and maternal uncles. Theoretically they are monogamous; marriage takes place only between members of different clans, but invariably within the tribe, infringement of the latter law being their greatest vice. The organisation of the Zuñi remains essentially maternal, the chief modification being the relaxation of the fierce tribal endogamy. The would-be bride is the chief suitor, as among the Tarahumari Indians of northern Mexico, where, according to Lumholtz, the maiden is a persistent wooer. Essentially the same stage is represented by the Seneca Indians, a more warlike tribe than the two last. The characteristic features of these and other American tribes organised on the basis of mother-descent, are monogamy, clan exogamy, tribal endogamy, the absence of bride purchase, and rudimentary personal inclination. Among the Indians of British Columbia, as described by Boas, mother-descent is merged with or passed into paternal organisation. A temporary exchange of property on the part of the groom, who is the suitor, occurs among the Kwakiutl, and the laws of monogamy, clan exogamy and tribal endogamy are materially relaxed. This tendency is increased among the Omaha and neighbouring Siouan Indians; individual inclination becomes dominant, and wife-purchase obtains, with a concomitant degradation of woman; finally, the monogamic principle is almost wholly lost. In all the higher forms there are various vestiges of antecedent customs, so that every stage can be traced in observance and decadence.

IT is pointed out in the *Bulletin of Miscellaneous Information* of the Royal Botanic Gardens, Trinidad, that the rainfall for that island is slowly but surely decreasing. The average rainfall for the decade 1862–71 was 66·715 inches; for the next decade (1872–81) it was 65·993, and for the third decade (1882–91) it was 65·037. The decrease indicated by the first and third values is 1·678 inches, or 251 per cent. during the thirty years from 1862 to 1891. Presuming that the same rate of decrease runs on for the next sixty years, Trinidad will then suffer from a rainfall diminished by about 8 inches. Mr. Hart points out that a rainfall decreasing at such a rate is alarming; and, if the inference is carried on, it follows that within a measurable distance of time Trinidad must become an arid desert as barren as the Great Sahara. The cause of the decrease is said to be the disappearance of the forests.

WE have received from Mr. A. L. Rotch an interesting pamphlet, reprinted from *Appalachia*, vol. viii., and entitled "The Exploration of the Air," containing a brief account of all the leading experiments, either in balloons, on mountains, or by means of kites, made for the purpose of solving such problems as decrease of temperature and humidity with elevation, the heights to which areas of high and low barometric pressure extend, and the circulation of the atmosphere at various heights; also containing good photographic views of some of the prominent observatories, and a diagram of comparative altitudes attained. The highest meteorological station in the world is that at El Misti, in Peru (19,200 feet), which was established by the Harvard College Observatory. It is impossible for observers to remain at this station, so it is provided with automatic instruments, which require only occasional attention. Among the other most notable mountain stations are Rocher des Bosses on the Alps (14,320 feet), and Sonnblick (10,170 feet). The only way in which the temperature and humidity of the highest regions can be obtained is by means of unmanned balloons, which have reached altitudes of over ten miles. Recent experiments by these balloons have given temperatures of 90° below zero of the Fahrenheit scale. Recent improvements in kites have allowed observations to be recorded at a height of nearly 4000 feet, and have revealed many interesting facts. It seems not improbable that this simple method of "sounding" the atmosphere will in the future be used, in connection with observations made at the earth's surface, in forming synoptic charts for forecasting weather.

THE *Oesterreichische Botanische Zeitschrift* for November 1896, gives some interesting particulars of Herr Sintenis's botanical expedition in Greece.

The second annual general report upon the mineral industry of the United Kingdom, for the year 1895, by Prof. C. Le Neve Foster, F.R.S., is published as a Blue Book. The report is a unique collection of statistics upon the minerals raised in Great Britain and Ireland, and the persons employed in mines.

AT the annual general meeting of the Geologists' Association, to be held on Friday, February 5, at University College, the President, Mr. E. T. Newton, F.R.S., will deliver an address on "The Evidence for the presence of Man in the Tertiary Period."

A NUMBER of good reproductions of photographs of lightning, and of effects produced by the discharge, accompany an article, by Mr. Jeremy Broome, in the February number of the *Strand Magazine*. In the *English Illustrated Magazine*, Mr. W. A. Horn gives a good general account of the results of the scientific expedition to Central Australia, the cost of which was generously defrayed by him. Some of the illustrations from the report on the geology and botany of the region traversed (see NATURE, p. 185) accompany the article.

THE third part of Mr. Sydney Rowland's "Archives of Clinical Skiagraphy" (the Rebman Publishing Company) has just appeared. It will be remembered that the publication consists of a series of collotype illustrations with descriptive text, representing applications of Röntgen photography to medicine and surgery. The new part contains Röntgen photographs of fracture of the olecranon treated by suturing with wire, fracture of lower end of humerus, with separation of the external condyle, a case of hip-joint disease, supernumerary toes, a double human monstrosity, united fracture of both bones of the forearm before and after union by wiring, and the cardiac area.

MR. W. L. DISTANT makes his bow in the January number of the *Zoologist*, and delivers his prologue as editor of the series commenced under his guidance. He inaugurates the new era in the life of our contemporary by announcing that the official reports of Natural History Societies will be discontinued. Prehistoric man, his past history, physical peculiarities, and connection with the old British fauna, is to be given his place in the pages; and, to show that our remote ancestors really ought not to be disregarded by zoologists, Mr. E. W. Brabrook contributes to the present number an article on "Man in Zoology." No longer is man to be considered as outside the domain of zoology. "Evolution," remarks Mr. Distant, "is now the established corner-stone of the zoological edifice," and upon it the new series is apparently to be built. Facts

are, however, as necessary as philosophy; therefore full space will be given to recording them, the only conditions being that they are original. These are admirable designs, and if future numbers of the new series carry them out as well as the opening one, a full measure of success will be the reward.

THE Smithsonian Report for 1894 has just been received. As is now well known, and it cannot be too widely known, the Report of the Smithsonian Institution not only exhibits the financial affairs, operations, and conditions of the Institution, but also comprises a selection of miscellaneous memoirs of interest to every one engaged in the promotion of knowledge. This appendix in the present Report runs into more than 600 pages, and is made up of reprints of thirty-seven papers, written by leaders in many branches of science. All these papers deal with important scientific work or problems, and they possess the additional advantage of being written in language easy of comprehension. Seventy plates illustrate the papers, and there are numerous figures in the text. The publication of such collections of papers as have been included in the Smithsonian Reports since 1889, embracing a considerable range of scientific investigation and discussion, is of enormous value to all who are interested in the progress of natural knowledge.

IN Part iv. of the quarterly *Journal* of the Sanitary Institute (vol. xvii.), just published, are several papers of interest. Small-pox and the beneficent effects of vaccination are the subjects of two papers. Dr. Arthur Newsholme describes a number of positive instances of the spread of enteric fever by means of sewage-contaminated shell-fish; Dr. Sims Woodhead urges the inspection of dairy farms, and the bacteriological examination of the milk therefrom, as well as of the agencies which distribute it; Mr. W. Hunting discusses tuberculosis in relation to public health; and Dr. H. Scurfield lays down an anti-tuberculosis programme. Among other subjects dealt with are the bacterial filtration of public water-supplies, by Mr. Wolf Defries; dangerous constituents of colliery air, by Prof. Frank Clowes; sanitation in Denmark, by Dr. J. Carlsen; the treatment of sewage (several papers); the planning of secondary schools, by J. Osborne Smith; the bacterial examination of water and sand filtration, by Prof. Percy Frankland, F.R.S.; the effect of cold weather upon health, by Dr. A. Lockhart Gillespie. All these papers were read at the Congress held at Newcastle-upon-Tyne last year.

AN important relation between the optically active forms of methylmannoside, $C_7H_{14}O_6$, and the inactive racemic form of the same substance, has been brought to light by Prof. Emil Fischer and L. Beensch. The active forms can be separately recrystallised from warm water without undergoing any change. When they are both dissolved in water so as to produce an inactive solution, crystals of the racemic form are deposited, provided that the temperature of the liquid is above 15°. If the temperature, on the other hand, be below 8°, the two active forms separate out in individual crystals, which can be mechanically separated, and some of which are found to consist of the pure dextro-compound, others of the pure lævo-compound. Both the active and the inactive forms crystallise without water, and this is the first instance in which this phenomenon has been observed in the absence of water of crystallisation. In all previously known cases the racemic form has crystallised with less water than the active forms, a fact which might be expected to favour its formation at a higher temperature.

THE name of glycogen may still convey to some the idea of the substance that forms grape sugar; but it is used in a wider sense in a recent work by Dr. Charles Creighton. The work is "Microscopical Researches on the Formative Property of Glycogen," and the first part of it, dealing with the physiological side of the subject, has just been published by Messrs. A. and C. Black. Not with the sugar-yielding character of glycogen, but with its tissue-making property, is Dr. Creighton concerned; and the present publication describes the researches of others and himself on this problem of glycogen in formative processes. The observations on the presence of this substance in hibernating animals furnish a few new facts. From the evidence so far obtained, Dr. Creighton states:—"We find that in hibernation glycogen is present, and may be abundant, in the liver, which is against the rule of starving animals; that it is present in some peculiar way in the muscular and pulmonary tissues, and that it is found in granules in fat-cells. Any attempted interpretation of these facts cannot but be hazardous while so many other relevant facts remain to be determined exactly; but it seems probable, as Voit has conjectured, for the hepatic glycogen, that the store of fat is utilised by being converted into glycogen. As to the hibernating gland, its function appears in some way correlated to the wasting of the fat-store during the winter, the gland-substance becoming physiologically most active in correspondence with the wasting of the animal's fat in general. We await the completion of Dr. Creighton's work before reviewing it.

THE additions to the Zoological Society's Gardens during the past week include two Four-horned Antelopes (*Petraceros quadricornis*, ♂ ♀) from India, presented by Colonel W. W. Lean; two Buzzards (*Buteo vulgaris*) from South Wales, presented by Mr. H. Edgar Thomas; two Carrion Crows (*Corvus corone*), British, presented by Mr. Alfred Greaves; a Golden Eagle (*Aquila chrysactus*) from Greece, presented by Dr. H. O. Forbes; a Goosander (*Mergus merganser*) from Holland, purchased.

OUR ASTRONOMICAL COLUMN.

OXYGEN IN THE SUN.—Herren Runge and Paschen have recently suggested (*Astrophysical Journal*, No. 5) a criterium by which the presence of oxygen in the sun may be directly ascertained. They have found that in a vacuum tube filled with oxygen, the line at 7775, discovered by Piazzi Smyth, has two components, the strongest being the most refrangible and the weakest the least refrangible; the wave-lengths of the three are 7772·26, 7774·30, and 7775·97. In the solar spectrum about this region there are, comparatively speaking, few lines, but, corresponding with the above wave-lengths, there is a triplet which has the same characteristic intensities. Herren Runge and Paschen think that their origin is probably not atmospheric, for the spectrum of the oxygen vacuum tube differs widely from the absorption spectrum of atmospheric oxygen. Mr. F. McLean has examined his photographs of the high and low sun, and has found that these lines do not depend on the altitude of the sun, which fact still further points to a solar origin. A crucial test would be to examine the opposite limbs of the sun, and find out whether any displacement of the lines occurs.

THE POLAR CAP OF MARS.—We have received the following information from America:—"A telegram received at Harvard Observatory, on January 11, from Lowell Observatory, now located near the city of Mexico, says that a rift has been observed since January 7 in the north polar cap of Mars in longitude 40°." This "rift" is probably similar to those observed at the opposition of 1894, in the southern cap. Prof. W. H. Pickering, with a 6-inch telescope, found one on May 22, crossing the cap from longitude 330° to 170°. This grew very considerably in size, measurements made on June 6 and 15 indicating a width of 100 and 350 miles respectively. Mr. Douglass also during the same month, June 10, detected a second and a third rift, the latter running from longitude 170° to 90°. The sequence of phenomena observed seems to indicate that they are due to the lower levels at the poles being uncovered; in this way, as the snow melts, the bare ground is exposed, appearing dark in contrast to the snow still lying on the more elevated heights. Their broadening is then a natural result of the departing snow, and indicates that the polar cap is at that time in a far advanced state of disintegration.

THE QUESTION OF CARBON IN BRIGHT LINE STARS.

THE spectrum of carbon is one which is subject to very great changes when examined under different experimental conditions, and an acquaintance with these variations is essential to an adequate discussion of the spectra of the heavenly bodies.

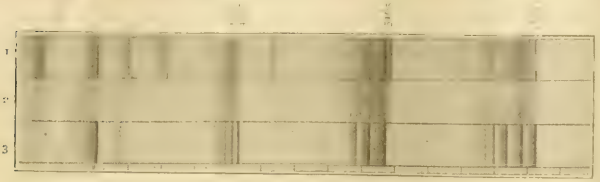


FIG. 1.—(1) Spectrum of mixture of hydrocarbons and oxy-carbon obtained from meteorites, with small coil and jar. (2) Spectrum of Comet III. 1881. (3) Spectrum of gases from meteorites, with large coil and jar (Vogel).

Every one knows the considerable development of the spectrum of carbon in most cometary phenomena; and there is a band which Dr. Vogel some years ago attributed to carbon, although it does not coincide with the most familiar carbon spectrum, that of the Bunsen burner. Dr. Vogel gave his reasons for this allocation, and illustrated them by a diagram[1] in which it is shown that in the spectrum of the comet, the blue band has its maximum about 470, and fades away nearly equally in both directions. If one's knowledge of the carbon spectrum were limited to that of the Bunsen burner, indicated at the bottom of the diagram, the comet band could not be ascribed to carbon.

But another spectrum of carbon, obtained by Dr. Vogel (given at the top of the diagram), shows the blue band of exactly the same form, and in the same position as that in the comet. Hence, Dr. Vogel argued that the blue band in the comets, though not coinciding with the carbon group at wave-length 4737, seen in a Bunsen flame, was still due to carbon.

When I was discussing the spectrum of the bright line stars in my general survey, a band in very nearly, if not absolutely the position of the cometary band, was found recorded. Most unfortunately I had completely forgotten Dr. Vogel's paper of 1881, and I set to work to study its origin for myself.

In the course of the previous thirteen years I had taken some hundreds of photographs of the spectrum of carbon compounds under a great variety of conditions; and I was driven to carbon because one of the most conspicuous features of the spectrum of many of the bright line stars is a broad blue band, a part of which falls within the limits of the group of carbon flutings at 4737, which is seen in the Bunsen, although its brightest part in the stellar spectra is about wave-length 468; that is, some distance further towards the blue than the brightest part of the Bunsen group. Forgetting Vogel's prior labours, I looked through my photographs, and found what he had found, that, under certain conditions, the maximum of the band is shifted, under some conditions of pressure and temperature, from 4737 to about 4685. One of my photographs, taken in December 1886, is reproduced in Fig. 2.

The spectrum at the top of Fig. 2 is the spectrum of alcohol vapour at a relatively high pressure; and among the most notable differences from the lower pressure spectrum at the bottom of the diagram, is the enhancement of the more refrangible part of the group of flutings commencing at 4737. This is still more marked in the spectrum at intermediate pressures, as shown in the middle spectrum in Fig. 2. In short, the brightest part of this group now agrees, very nearly, with the blue band of some of the bright line stars. It is very difficult to estimate the middle of such a broad, diffuse band as that in question; but the wave-length of the brightest part is approximately 4685.

As Dr. Vogel had previously done for comets, I was particularly careful to point out that the carbon band in the bright line stars was not seen under the same conditions as that in the Bunsen flame.[1]

I next append some observations of the band in both comets and bright line stars:—

Comet.	Maximum of band.	Observer.	Star.	Brightest part.	Observer.
Winnecke. 1868	469	Huggins	} No. 3821	469	Huggins
Comet IV. 1873	469	Vogel			
Comet III. 1881	468·5	Vogel	} No. 4001	468	Huggins
Comet III. 1881	468	Copeland			
Comet IV. 1881	470	Copeland			

Notwithstanding the difficulty of determining very exactly the brightest part of a diffuse band, it will be seen that the bands in two of the stars are exactly coincident with bands which have been measured by trustworthy observers in three comets. In the fifth comet, named above, the variation in the wave-length of the band is not greater than that between two individual measures in stars.

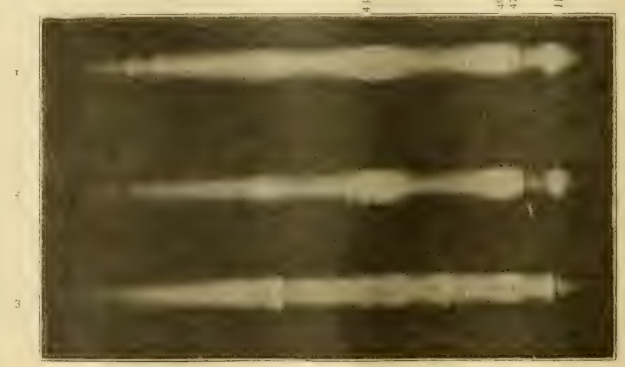

FIG. 2.—Spectrum of alcohol vapour. (1) Highest pressure. (2) Intermediate pressure. (3) Lowest pressure.

The fact that, so far as I know, this explanation, the whole credit of which is due to Dr. Vogel, has never been called in

[1] Potsdam Observations, I. II. p. 173.

[1] In 1888 I wrote: "This band is evidently the bright band of carbon, commencing at 474, with a maximum about 468, as observed and photographed at Kensington" (*Roy. Soc. Proc.*, vol. xliv. p. 35). Later in the same year I added: "It is necessary to state that the maximum luminosity of the blue band, under some conditions, is about 468. . . . The conditions under which this band has its maximum luminosity at 468 in Geissler tubes seem to be those of maximum conductivity" (*Roy. Soc. Proc.*, vol. xlv. p. 167).

question in relation to comets, would indicate that it may be equally unobjectionable in the case of the bright line stars.

But there was more evidence behind with regard to the other carbon flutings.

The spectrum of carbon does not consist of the blue band alone, so that some account must be rendered of the other parts of the carbon spectrum, more especially of two groups of flutings in the green. We should not expect the green flutings to be so easily visible as the blue in stars, for the reason that they fall in the brightest part of the continuous spectrum; while in comets where there is little continuous spectrum, they are the most conspicuous bands.

In the star BD + 36° 3956, for example, Vogel's observations gave indications of the two green bands which are seen in the spectra of carbon compounds, and are the chief characteristics of the spectra of comets at mean distances from the sun.

It was in 1890 that Dr. and Mrs. Huggins formulated objections, based on some new measures, to my view as to the probable carbon origin of the blue band in the bright line stars.

Thus, in two cases they found, as Vogel had found before them, that the brightest band was still more refrangible than the brightest part of the modified carbon band; but in each of these cases they found, also, a band about the position of 4685.

As a result of their work, they made the following statement:[1] "Our observations appear to us, however, to be conclusive on the main object of our inquiry, namely, that the bright blue band in the three Wolf-Rayet stars in Cygnus, and in DM + 37° 3821, is not coincident with THE BLUE BAND OF THE BUNSEN FLAME."

The capitals are mine. It will have been seen how carefully Vogel in the case of comets, and myself in the case of stars, had pointed out that it was not a question of the Bunsen flame!

Dr. and Mrs. Huggins do not admit that the observed variations of the band in the carbon spectrum are sufficient to explain the position and appearance of the band at 4685 in the stars, basing their objections on experimental evidence afforded by Hasselberg.

Vogel's researches, as well as my own, on the carbon spectrum, however, indicate a much greater concentration of luminosity of the band about 4685 than appears to have been observed by Hasselberg. But this is not to be wondered at, since every change in the experimental conditions may have an effect on the spectrum.

I am not aware of any other objection to my view than the above, and it will be remarked that Dr. Huggins is silent altogether in regard to the existence of the band in comets.

Very fortunately for science, a great mass of new work on this part of the subject has been brought together since the Meteoritic Hypothesis was published, chief among the workers being Prof. Campbell.

Let us turn to this new work, therefore, and see in what direction it tends.

We may take the case of one of the brightest stars of this class in Argo, the spectrum of a star which my friend Respighi and myself were the first to see on a very hot night in Madras in 1871, a beautiful spectrum with many bright lines. Prof. Campbell, in 1893, included the study of this bright line star in his work at Lick. What is his result with regard to the band at 4685? He finds a band at 4688.[2] In my first discussion I took the position of the brightest band as 4682, depending upon measurements made by Ellery, at Melbourne, in 1879. In a more general examination of all the Wolf-Rayet stars in 1894,[3] he finds a band at 4688 to be the most constant feature, and in some stars it appears almost alone! This in itself would be almost sufficient to prove carbon.

Prof. Campbell does not discuss the origins of the lines and bands which he has measured, but it will be seen that for such a diffuse band as that in question, his wave-length 4688 does not differ materially from that already given for the modified carbon band.

There is now, therefore, in the light of the newest and best work, no question about the fact that in the bright line stars there is a band at 468, the wave-length of the modified carbon band; and this was my original contention.

The new measures obtained by Dr. and Mrs. Huggins, therefore, do not affect my views as to the origin of the blue band of the bright line stars recorded at places varying between λ 468 and λ 469.

[1] *Roy. Soc. Proc.*, vol. xlix. p. 46.
[2] *Astronomy and Astrophysics*, 1893, p. 555. [3] *Ibid.*, 1894, p. 448.

With regard to this band, then, the first conclusion is now firmer than ever, strengthened as it is by Campbell's new work.

Dr. and Mrs. Huggins object to another point.

It has already been remarked that Vogel's observations suggested the presence of the green flutings in one of the stars.

On this point Dr. and Mrs. Huggins remark that, when observing the bright line stars with small dispersion, "it might easily be supposed that the spectrum is brighter at the position of the green carbon band"; with high dispersion, however, they can see "no sensible brightening" in that part of the spectrum. In the case of another line distinctly seen with small dispersion, they remark that with high dispersion it was so indistinct that they could not determine whether it was D or D_3;[1] so that their observations do not demonstrate the absence of the green fluting of carbon.

Observations made at Kensington strengthen the idea that the green flutings are present in the spectra of bright line stars. When high dispersion is employed, flutings are weakened in much greater proportion than lines; so that comparatively small dispersion must alone be employed in observations of this kind.

Campbell shows that while the average position of the brightest blue band in one group of stars is 4688, in another group it is 4652. These two bands are frequently associated in the same spectrum, but occasionally each occurs by itself.

As to those stars in which a band appears about λ 465, it is quite possible that we may still have to deal with carbon. At present I am not aware of any experimental evidence; but the possibility of a band at this wave-length, under a certain still untried condition is suggested by the fact that a band about this position was observed in Brorsen's comet in 1868 and 1879.

But the existence of a band at 465 surely does not negative the existence of a band at 4685!

The present position of the question of carbon, then, is this. The new work of Campbell justifies us in associating, not only in comets, as first suggested by Vogel, but in bright line stars, as suggested by myself, the blue bands at 468 with carbon; and a study of the spectra of comets suggests, but does not demonstrate, that the other band at 465 has the same origin. The feeble appearance of the green bands is no doubt due to their superposition upon the brightest part of the continuous spectrum.

Hence the idea of the chemical and physical kinship of comets, nebulæ, and bright-line stars is strengthened.

J. NORMAN LOCKYER.

THE SAVING OF VANISHING KNOWLEDGE.

IT is well from time to time to take stock of our knowledge and of our methods of inquiry, to see whether we are working on sound lines. As the business man finds it necessary to periodically go over his stock and balance his books, so, too, the scientific man, especially the biologist, should perform an analogous operation, lest perchance he find out too late that he has been entering on a comparatively unprofitable line of work, or has been neglecting valuable opportunities. While it is impossible to say what scientific work is ultimately unprofitable, it may not be difficult to suggest that particular subjects for investigation are of more immediate importance than others.

Let us for the moment divest ourselves of all preconceived ideas and pet fancies, so as to discover what is at the present time the most urgent need of science. In order not to complicate the question, we will dismiss the practical applications of science by admitting that they are of immediate importance. This leaves the field clear for scientific subjects which are studied solely for their own sakes.

We can, perhaps, gain a clearer view of the question by looking at it from the standpoint of our successors—What will be the opinion of the naturalist of a hundred, or of a thousand, years hence? What is the scientific work that he would wish us to have undertaken? This question is an easy one to answer.

He would not consider it very necessary for us to elucidate the structure, development or physiology of every common animal; these matters can be done at any time. The investigation of the life in the oceans—whether on the surface, in shallow water, or in abysmal depths—can be done by him as well as by us. We may safely leave for the present the problems of the Ant-

[1] *Roy. Soc. Proc.*, vol. xlix. p. 44.

arctic polar basin; if this generation does not learn the secrets of the palæocrystal ice, another can and will do so.

Our future naturalist will certainly and most justly complain if we busy ourselves with problems that can wait, that he can solve as well as we, and at the same time neglect to do that work which we alone can do. Our first and immediate duty is to save for science vanishing knowledge; this should be the watchword of the present day.

Those students of botany, zoology, and anthropology who have at all considered the matter, are impressed with the fact that the present is a very critical time for the native flora and fauna of many parts of the world. Owing to the spread of commerce, the effects of colonisation, and the intentional or accidental importation of plants and animals, a very rapid change is affecting the character of the indigenous life of numerous districts. This is notably the case in oceanic islands, the area of which is often extremely limited, and as a consequence the native forms are the more likely to be swamped by the immigrants; but it is just those spots which are of especial interest to the naturalist, on account of their isolation from the great land areas. Thus the flora and fauna of many of the districts most interesting to the field-naturalist are in our day becoming largely exterminated before they have been adequately recorded. The investigation of disappearing animals and plants can, in many cases, be undertaken by us alone—and even now much has disappeared and more is fast passing away. It is, perhaps, scarcely necessary to point out that this investigation is not a matter of interest to the systematist only, but it is of great importance in connection with the problems of the geographical distribution of animals and plants which open up such fascinating vistas of the extension of continents in former ages, and of their partial submergence; not to speak of the bearing of specific and individual varieties on the intricate questions of the origin of species; or the adaptation of those peculiar forms to their particular localities, and those wonderful inter-relations between plants and plants, plants and animals, or between animals and animals, and between all and their environment.

Some years ago a Committee was appointed to investigate the zoology of the Sandwich Islands, and they sent out Mr. R. C. L. Perkins, who has done most excellent work. His researches in the Hawaiian group prove that quite a noticeable decrease in the indigenous fauna is taking place each season. The district around Honolulu was perhaps originally the richest in endemic forms, but now introduced forms are in vast preponderance; the distinctive fauna of the plains, if there was one, has quite disappeared. Captain Cook found certain birds, for example, near the shore; of these, some are extinct, and others are to be found only in the mountains. In a letter recently received, by Dr. D. Sharp, dated from Lihue, Kauai, he states: "This place has been a dead failure. The country where I camped here was a low-lying, densely-covered forest bog-land, at first sight a paradise for Carabidæ (ground beetles), and differing from any other place known to me. Its fauna is entirely lost for ever. I turned during my stay thousands of logs, any one of which at 4000 feet would have yielded Carabidæ; of all these there was not a single one under which *Pheidole megacephala* had not a nest, and I never beat a tree without this ant coming down in scores." This is an introduced ant which is overrunning the islands, and which exterminates the native insect fauna. Mr. Perkins finds that earwigs alone can withstand this ant, and his only chance of collecting endemic insects is to get ahead of the ant. The area of the whole group is somewhat larger than Yorkshire. If the diminution of the fauna is so marked in such a comparatively large group as the Hawaiian Islands, how much greater must it be in the small islands.

Mr. Knight, in his entertaining book "The Cruise of the *Falcon*," describes the prostrate forests of the island of Trinidad in the South Atlantic. We never can know what was the nature and extent of this vanished flora and fauna.

What is taking place in the small islands holds good to a somewhat less extent for the larger ones. In New Zealand the Government is taking steps to preserve certain well-known vestiges of its ancient fauna which are in imminent danger of extermination; but it does not interest itself in the inconspicuous forms, which are subject to the same danger, nor does the New Zealand Government systematically investigate the existing fauna of the group.

It is necessary that such investigations should be undertaken by competent naturalists. They should not only be good collectors, but keen observers, in fact, naturalists in the true sense of the term; for unless the work is well done, it had almost be better left undone. There are many examples of collecting being so imperfectly done as to lead to very erroneous conclusions. It takes time for a naturalist to become acquainted with the local types. The endemics do not show themselves, as usually the conditions of life are such that insects, for example, live retired lives and are not seen, while those that manifest themselves are often foreigners.

The extermination of animal life is more rapid and striking than that of plants, but what has been stated for animals must be applied to plants as well.

Not less important than the foregoing is the study of the anthropology of these districts. The Tasmanians have entirely disappeared, and we know extremely little about this interesting people. In many islands the natives are fast dying out, and in more they have become so modified by contact with the white man and by crossings due to deportation by Europeans, that immediate steps are necessary to record the anthropological data that remain. Only those who have a personal acquaintance with Oceania, or those who have carefully followed the recent literature of the subject, can have an idea of the pressing need there is for prompt action. No one can deny that it is our bounden duty to record the physical characteristics, the handicrafts, the psychology, ceremonial observances and religious beliefs of vanishing peoples; this also is a work which in many cases can alone be accomplished by the present generation.

The late Prof. H. N. Moseley was so impressed with this fact during his voyage on H.M.S. *Challenger*, that he concluded his "Notes by a Naturalist on the *Challenger*" by pointing out that the physical conditions and fauna of the sea can be investigated at leisure at any future time. "On the surface of the earth, however, animals and plants and races of men are perishing rapidly day by day, and will soon be, like the Dodo, things of the past. The history of these things once gone can never be recovered, but must remain for ever a gap in the knowledge of mankind. The loss will be most deeply felt in the province of Anthropology, a science which is of higher importance to us than any other as treating of the developmental history of our own species. The languages of Polynesia are being rapidly destroyed or mutilated, and the opportunity of obtaining accurate information concerning these and the native habits of culture will soon have passed away. The urgent necessity of the present day is a scientific circumnavigating expedition which shall visit the least-known inhabited islands of the Pacific, and at the same time explore the islands which yet remain almost or entirely unknown as regards their botany and zoology; these promise to yield results of the highest interest if only the matter be taken in hand in time."

There is no difficulty in finding men willing and competent to undertake such investigations if the funds were forthcoming; experience has shown that an annual sum of at least 400*l.* is necessary to equip and maintain one naturalist.

Here, then, is a great opportunity for the millionaire. No one doubts that the work is worth doing; it is essential that it should be done at once: capable men are ready to undertake it—only the means are lacking.

The British Association has appointed a Committee to report on this matter, of which Sir William Flower, Director of the Natural History Museum, South Kensington, is the Chairman, and the present writer the Secretary; so there exists a machinery ready to be put in action when funds are available. Will not one wealthy man, or a syndicate of rich men, contribute to do this work for the world? The opportunity if neglected is lost for ever.

A. C. HADDON.

SIR MARTIN CONWAY'S CROSSING OF SPITZBERGEN.

SIR MARTIN CONWAY read a paper on the first crossing of Spitzbergen at the meeting of the Royal Geographical Society on January 25, illustrating his description by a series of fine lantern slides of Spitzbergen scenery. He landed at Advent bay, accompanied by Dr. J. W. Gregory, Mr. E. S. Garwood, Mr. A. Trevor-Batty, and Mr. H. E. Conway, two Norwegian sailors, and two ponies. The descriptions of previous travellers had led him to expect a series of boggy coast valleys leading up to an interior plateau covered with snow or ice, on which sledging would be practicable. The actual conditions were very different. The northern and southern parts of Spitzbergen are, in the main, covered with great accumulations of

ice, except along the west shore of Wijde bay, where is a relatively fertile area. The middle of the island, west of the main watershed, is a region of boggy valleys, fertile slopes, and mountain ridges, or the remains of a high plateau. The nature and interest of this country can be shown by a few specimen areas. The east shore of Wijde bay is formed by a long and very uniform slope, about 1000 feet high. The ice-sheet almost reaches the edge of this slope, except at a few places where the plateau has been broken down into valleys, whereby tongues of ice reach or approach the sea. That is an example of a plateau protected from denudation by ice. Along the north-east side of the Sassendal there is a similar plateau, from which, however, the ice-sheet has been withdrawn in recent times. Denudation has begun, and the plateau is being cut down by narrow and precipitous cañons, from which it derives the name Colorado Berg. These cañons are not being gradually lowered, but they are gradually creeping back. However short, all are practically of the same depth. It is at their heads that they are formed. Each is eating its way back with considerable rapidity, and the whole is the first stage of the formation of a mountain group.

From the whole area west of the Sassendal, between it and Advent bay, bounded on the north by Ice fjord, and on the south by Advent dale, the ice that once covered it appears to have been gradually withdrawn, beginning from the west. As one goes westward one comes to mountains in a more advanced stage of manufacture. The hills that look down upon the Sassendal are the bluff-fronted remains of a plateau, only a little more cut down than the Colorado Berg. Except in two cases, the valleys that penetrate them from the Sassendal are short. Further west come rounded hills, such as Mount Lusitania. Beyond De Geer valley are maturer peaks, with clearly defined arêtes and faces such as are familiar in ordinary mountain regions.

Where mountains are most developed valleys are oldest. Advent dale may be taken as type of these. As the ice retreated eastwards, Advent dale widened and crept back, receiving the drainage of a constantly developing valley-system, whose eastern watershed ran close behind the Sassendal bluffs. Later on the Sassendal tributaries became more active, and ate their way back, stealing one after another of the headwaters of Advent dale. The Esker valley is a good instance of this. It was formerly drained to Advent dale; now it drains in the opposite direction. Brent pass divides the drainages, but will not long continue so to do, for already a small stream, descending almost on to the pass, is in process of being stolen by the Esker. It now divides its waters upon its fan when in flood, one stream going to Advent dale, the other to the Esker. Fulnar valley, which formerly drained into Agardhs bay, has been similarly invaded by the Sassendal, and many more instances might be quoted.

The great interest, therefore, of this peculiar island of temperate climate in the midst of Arctic ice-sheets, lies in the fact that there is one of the very best examples in the world of the processes of mountain and valley manufacture. This fact altered the plan of the expedition, and showed that it was a far more important matter to make a fairly detailed examination of one portion (in itself, however, not inconsiderable) of Spitzbergen, than to scamper hurriedly across two or three separate belts. Sir Martin Conway and his companions crossed from sea to sea along three different lines; but, instead of being as far as possible from one another, these lines were so arranged that each should display the flank of the next. The crossings were from Advent bay to Van Mijen bay, from Van Mijen bay to Sassen bay, and from Sassen bay to Agardhs bay and back, finally returning along the shore of Sassen bay to Hyperite Hat, and completing the work by expeditions into the heart of the important mountain region which has been already referred to.

Sir Martin Conway proceeded to describe the incidents of the various journeys across the island, the journey being made both wearisome and dangerous by the constant rain, the boggy floors of the valley and the still more treacherous slopes of rotten snow. Thawing was going on very rapidly, and the rivers were so numerous, that fifty-two, which required to be forded, were counted in a single mile near the head of Advent dale. Some gleams of sunshine allowed of comprehensive views being obtained over the maze of valleys and broken plateau. The party carried on much of their work separately, thus being able not only to survey a large part of the island for the first time, but also to devote special attention to the geology and the conditions of the numerous large glaciers and innumerable moraines which were encountered.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. W. N. Shaw, F.R.S., has been appointed a member of the General Board of Studies. Mr. Middleton-Wake, the Sandar's Reader in Bibliography, will this term give a course of four lectures on the invention of printing, with special reference to book-illustration. Mr. C. H. Robinson, who has been elected University Lecturer in the Hausa language, will give an inaugural lecture on the Hausa people on February 2. Mr. E. J. Stone, F.R.S., and Prof. J. J. Thomson, F.R.S., have been nominated as examiners for the Adams prize to be awarded in 1899. Dr. Somerville is this term lecturing on agriculture and forestry at the University Chemical Laboratory. He announces also a special lecture on the "finger and toe" disease of turnips on February 6.

A SPECIAL educational supplement is published with the *Academy* of January 23. In it will be found some suggestive notes on the use of illustrations and models in teaching, and records of scholastic events in the principal public schools during the third term of 1896.

THE annual general meeting of the Association of Technical Institutions was held in the Clothworkers' Hall, London, on Friday, January 22, when the Right Hon. A. J. Mundella, M.P. (the retiring President), presided over a large attendance of members. Mr. Henry Hobhouse, M.P., was elected President for the year 1897, and delivered his inaugural address. It was resolved to request the Council to take into consideration and to report to the next general meeting as to the best means of promoting full recognition of the attainments of technological students, and also as to the best method of securing a closer co-operation with the Examination Board of the City and Guilds of London Institute; in considering this important matter the Council is to have power to co-opt such persons as it may deem desirable. The Council for the year was elected as follows:—President: Mr. Henry Hobhouse, M.P. Vice-Presidents: The Right Hon. A. J. Mundella, M.P., Mr. W. Mather. Treasurer: Councillor R. F. Martineau. Hon. Secretary: Prof. J. Wertheimer.

A NOTEWORTHY event in the annals of technical education in the United States will be the forthcoming celebration of the twenty-fifth anniversary of the Stevens Institute of Technology, on February 18 and 19. From the *Journal* of the Franklin Institute we learn that the institute was founded by the late Edwin A. Stevens, of Hoboken, N.J., and in 1870 the erection of a building was commenced. Dr. Henry Morton, at that time secretary of the Franklin Institute, was tendered the presidency of the institute, and gathered a faculty of eight members about him. To this number others have, from time to time, been added as the work of the institute increased, until at the present time the faculty includes twenty-two professors and instructors. The total number of student graduates is 675, and the number in attendance during recent years has been about 260 each year. The Stevens Institute has always taken high rank among the institutions devoted to technical education in the United States, and its twenty-five years of successful effort is amply exemplified in the work accomplished by its graduates in all departments of mechanical and electrical engineering.

FROM the Berlin correspondent of the *Lancet* we understand that there is some uneasiness in German University circles. In Germany a university student has to pay a fee each half-year for every lecture he attends, and this money becomes the property of the individual teacher. In addition to the students' fees, the professors receive a fixed salary from the Treasury; but the great majority of associate professors and *privat-docents* do not get any remuneration from the Government. In order to redress this inequality, the Government proposes to introduce a Bill providing that lecture fees exceeding 4000 marks (200*l.*) in Berlin University and 2000 marks (100*l.*) in the provincial universities shall be divided between the lecturer and the Treasury. The fund thus obtained will be used to increase the remuneration of the teaching staff of the university. The announcement of this contemplated innovation has caused a sensation among the members of the universities. They point out that the new measures will induce the members to raise the fees, and that the expense of university education will thereby be increased. The Bill would also restrict the liberty and freedom of action

at present possessed by the universities, and place them in a position of dependence on the Government. Although it is intended that the new regulations shall only come into operation gradually as new appointments are made, and shall not be applicable to the professors who already occupy chairs, the effect has been to cause so much uneasiness in university circles that the Government may possibly abandon the proposal.

THE annual general meeting of the Association of Technical Institutions was held on Friday last. Mr. Hobhouse, M.P., in the course of his presidential address remarked that he hoped the rising generation of agriculturists, as of other classes, would listen to the wise advice given them by such men as the Duke of Devonshire, Lord Rosebery, and Sir Henry Roscoe, and would avail themselves of every opportunity to acquire skill and apply knowledge in adapting their industry to the altered conditions of the times. As to how far this kind of instruction was to be carried, he urged that they should extend and advance their instruction as far as ever their funds would permit. It was somewhat extraordinary to see the same men who were willing to pour money out like water on new ironclads and regiments for meeting the remote contingency of an invasion by foreign troops grudge a few thousands a year for checking, and, if possible, defeating, the immediate and actual invasion of our country by foreign products and foreign workmen. As to the conditions under which technical instruction should be given, he pleaded that specialised training should not begin too early in life, but should as far as possible be based on a solid foundation of literary and general culture; and they should bear in mind the importance of a well-balanced and truly educational curriculum. They would, further, all agree that in a properly-managed institute there should be no cramming for examinations; that neither children nor adult pupils should be treated as grant-earning machines; and that they ought to aim at securing that continuous "low-pressure" system of work that was induced by enlightened and helpful inspection rather than an intermittent "high-pressure" system resulting from mechanically-conducted paper examinations.

THE Technical Education Committee of the Derbyshire County Council have already provided definite systems of applied technical instruction for agriculture and mining—the two great industries of the county, but they have found a difficulty in doing anything for the smaller and more scattered industries. For these it is often not possible to do more than provide general secondary education and instruction in scientific principles. From a report just issued by the Committee, it appears that in the north-west of the county there is, in a comparatively small area, a large development of the calico-printing industry, involving a capital expenditure of over half-a-million, and giving employment to 2000 hands. Recent inquiry has shown a definite want of technical instruction in this industry. At a meeting of manufacturers, attended by Mr. Percy Hawkridge, the Organising Secretary, it was shown that they obtain their colours from Germany, and that their composition is not known in this country by the people engaged in their use. They are bought and used in accordance with instructions supplied by the German colourist. Most of these colours are, however, definite chemical compounds derived from coal-tar. They are understood thoroughly by English chemists, and there is no valid reason why they should not be produced in this country, in association with the industries employing them. Indeed, the Committee reports that, even with the ordinary chemical appliances in use at New Mills, valuable results have been achieved. As a result of the meeting referred to, it has been resolved to ask the Derbyshire County Council to construct a laboratory to be specially devoted to this work. The scheme commends itself to the Committee on account of its decidedly practical nature, and also on account of the unique development of the calico-printing industry in the neighbourhood of New Mills.

SCIENTIFIC SERIALS

American Journal of Mathematics, vol. xix. 1 (Baltimore, January, 1897).—Theorie der periodischen cubischen Transformationen im Raume R_3, by S. Kantor, contains a full account (in 59 pages) of the theory on the lines of the same author's Theorie der endlichen Gruppen von eindeutigen Transformationen in der Ebene (1895).—Mr. Basset, in theories of the action of magnetism on light, discusses the theories of Maxwell, Fitzgerald, and Larmor. His object is twofold. First, he subjects Mr. Larmor's theory to a searching examination, and maintains that instead of being an improvement on its predecessors, it is open to a variety of additional objections and defects. In the next place, by means of a modification of the fundamental hypothesis, he proposes to show that the theory of Rowland and himself may be placed on a perfectly satisfactory basis, and that the difficulty with regard to the discontinuity of the tangential component of the electro-motive force at an interface may be removed.—In the article on the roots of Bessel- and P-functions, Mr. Van Vleck confines his attention to those functions which are symmetrical in their properties with respect to the real axis of the complex variable. The first part of his work aims at proving that between two successive positive or negative roots of $J_n=0$ there lies one, and only one root of $J_n+_1=0$. He gives an extract from Gray and Mathews' treatise on Bessel Functions, but in so quoting he spells each author's name incorrectly. He proves, in the second part of his article, a similar theorem for contiguous Riemann P-functions.—Herr Kantor contributes a short note, Ueber Collineations gruppen an Kummer'schen Flächen.—Two more notelets are: note on linear differential equations with constant coefficients, by F. Franklin; and on certain partial differential equations connected with the theory of surfaces, by T. Craig, the editor.—An excellent portrait of Prof. L. Fuchs faces the title-page.

American Journal of Science, January.—The worship of meteorites, by H. A. Newton. (This lecture, delivered by the late Prof. Newton in 1889, has not hitherto been published. We hope to be able to refer to it fully in a later number.)—The spectra of argon, by J. Trowbridge and T. W. Richards. The two characteristic spectra of argon were studied by means of a high-tension accumulator of 5000 cells, which gives a more uniform discharge than either the induction coil or the influence machine. A tube 15 cm. long was filled with the gas. The red glow of argon was readily obtained with a voltage of about 2000. At higher pressures a higher voltage is required; but when the discharge has once set in, it may be continued with lower voltages. The introduction of a capacity in the circuit made no difference as long as the condenser was quiet; but as soon as the condenser began to emit its peculiar humming sound, the beautiful blue glow so characteristic of argon immediately appeared. Examined by a revolving mirror, this glow was seen to consist of intermittent discharges. The blue glow was changed to red by introducing a small coil of about 8 ohms resistance and a self-induction of ·015 henry. The same conversion may be brought about by introducing a simple resistance or self-induction, or by increasing the pressure of the gas, and consequently its resistance. The blue glow may also be produced by sending an exceedingly strong current through the tube for very short intervals. In this case it is probably the capacity of the battery itself which produces the necessary oscillations. A tube containing argon at suitable pressure shows the blue colour at once on being brought near a Hertz oscillator giving 115 million oscillations per second. The tube may be used as a sensitive detector of electric waves, and the author proposes to give it the special name of talantoscope.—Some queries on rock differentiation, by G. F. Becker. The homogeneity of vast subterranean masses, called for by the hypothesis of differentiation, is unproved and improbable. The difference between well-defined rock types are more probably due to original and persistent heterogeneity in the composition of the globe. Hypogeal fusion and eruption tend rather to mingling than to segregation, and transitional rocks may be accidental mixtures of the diverse primitive masses composing the earth's crust.—Igneous rocks from Smyrna and Pergamon, by H. S. Washington. Describes an augite-andesite rock from Mount Pagos, near Smyrna, and a biotite-dacite from Pergamon.—Revision of the genera of the Ledidæ and Nuculidæ of the Atlantic coast of the United States, by A. E. Verrill and K. J. Bush. Describes five new genera, chiefly belonging to the family of Ledidæ, from the U.S. Fish Commission dredgings. The paper is accompanied by twenty-two diagrams.—An experiment with gold, by M. Carey Lea. Of a 10 per cent. sodium hypophosphite solution, 15 cc. are placed in a beaker, and 1 cc. of a gold chloride solution containing 1 gr. of gold to 10 cc. of solution is added, and then one drop of H_2SO_4. As soon as the solution begins to darken, 30 cc. of water are added. The solution then assumes a deep green colour, due to very

finely divided blue gold suspended in the yellow solution.—Note on a new meteorite from Sacramento Mountains, Eddy County, New Mexico, by W. M. Foote. This was seen to fall in 1876. It weighs 237 kgr., and measures about 80 × 60 × 20 cm. It contains 91·39 per cent. of iron, and shows splendid etching figures.

Bulletin of the American Mathematical Society (December 1896).—Dr. W. J. A. Young reviews the "Introduction à l'étude de la Théorie des Nombres et de l'Algèbre supérieure," by Messrs. Borel and Drach. This is an interesting work founded on lectures by M. Jules Tannery. These lectures were delivered during the scholastic year 1891–2, before the students of the third year, in the École Normale Supérieure. Dr. Young characterises it as a book to be read and not to be used as a book of reference. The scanty table of contents offers but little assistance to one, who, without having read the book, or at least having familiarised himself with the details as to its contents, wishes to consult its pages on a specific question. It gives clear and concise outlines of general principles stripped of illustrations and amplification. One great blemish appears on the surface, for hardly any references are said to be given either to the original sources of the material used, or as guides to those who wish to study the subject further. Some of the references which are given are not as clear as could be wished: thus the proof of the proposition that every integer can be expressed as the sum of four or fewer squares, which is based on the properties of continued fractions, and which makes use of determinants, is assigned to Mr. Smith. To those who know this is, of course, the proof by Prof. Henry Smith. To add to the unsatisfactoriness, no indication is given of the way in which "Mr. Smith" expressed his proof. Many such blemishes (apparently) are to be met with, which mar a book of considerable value.—"Quaternions" is a highly commendatory notice of Prof. Hathaway's "Primary Quaternions," by Prof. J. B. Shaw.—Prof. Hathaway briefly discusses three recent text-books: viz. "Elements of Geometry," by G. C. Edwards; "Plane and Solid Geometry," by W. W. Beman and D. E. Smith; and "Plane and Solid Geometry" (suggestive method), by C. A. Van Velzer. Each book appears to embody some new and distinctive features.—Dr. G. A. Miller, in an article on several theorems of operation groups, continues his work on the lines of his recent contributions to the *Quarterly Journal of Mathematics* (vol. xxviii.).—"Numerically regular Reticulations upon Surfaces of Deficiency higher than 1" is a short note on a generalisation of Euler's relation for convex polyhedra, by Prof. H. S. White.—The usual interesting news, under notes and publications, closes the number.

Wiedemann's Annalen der Physik und Chemie, No. 1.—On the theory of stationary electric waves along wires, by P. Drude. Electric waves are not totally reflected by a bridge laid across the wire system. They undergo a displacement of phase and a diminution of amplitude, which depends essentially upon the ratio of the length of the bridge to that of the wave. Short waves, like those in water, are greatly damped by reflection. The absorptive power of a substance for electric waves may be measured by noting the number of nodes observable along the wire.—Treatment of high-tension accumulators, by L. Zehnder. The accumulators described by the author several years ago must not be charged by stronger currents than 0·1 ampere per cell. The creeping up of acid along the lead may be prevented by spreading the plates with vaseline while hot. The copper wires may be similarly protected from mercury by burning off the latter and covering with vaseline. An important precaution against the deterioration of the battery is never to leave the cells coupled in series or single. They should be connected in parallel when not in use.—Dielectric constants at low temperatures, by R. Abegg. The specific inductive capacities of all substances increase as the temperature falls, and it is possible to approach the high dielectric constant of water by cooling other dielectrics to low temperatures.—Magnetic induction of horizontal discs rotating in the earth's field, by F. F. Martens. Describes a new method of measuring magnetic hysteresis and viscosity, the disc being a limiting case of the ellipsoid of revolution.—Absolute thermal conductivity of air, by E. Müller. Investigates all the sources of error in the vacuum-thermometer method, and tests the variations used by Winkelmann and by Kundt, Warburg and Graetz. The former method was found unsatisfactory, and the latter, which eliminates radiation by determining it absolutely *in vacuo* and deducting it, gave values which are too small. Taking into account the residual mercury vapour and the newly-determined specific heat of the glass employed, the author finds the conductivity of air to be 0·000056 in C.G.S. units.—An attempt to separate the two constituents of cleveite gas by diffusion, by A. Hagenbach. Diaphragms of gypsum having been found unsatisfactory owing to contraction, compressed powdered graphite was used instead. The original density of the gaseous mixture being 2·315 (H = 1), that of the diffused gas was 2·032, and of the undiffused gas 2·576. The author believes that he has succeeded in a partial separation of the constituents of cleveite gas by this means.—Diffusion coefficients of some gases for water, by G. Hüfner.—Corresponding temperatures, by J. A. Groshans.—Elasticity and light, by P. Glan.

IN the *Journal of Botany* for December 1896, Mr. W. A. Clarke completes his "First Records of British Flowering Plants"; and two new species (?) of *Rubus* from Ireland are described by the Rev. W. Moyle Rogers. In the number for January 1897, Mr. W. P. Hiern gives a list of plants (flowering plants, Vascular Cryptogams, Muscineæ, and Fungi) gathered in the Isle of Man; Miss A. L. Smith describes some microscopic fungi new to or rare in Britain; Mr. J. Ll. Williams has an interesting note on the intoxicating effect produced on certain kinds of humble-bee by the honey of flowers belonging to the Compositæ and Dipsacaceæ.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, January 22.—Prof. Ayrton, Vice-President, in the chair.—Mr. Croft gave an exhibition of some simple apparatus. The exhibition included an ingenious form of clip to fit on an upright retort stand; a Nicol used for projecting the rings and brushes in crystals, with which it is sufficient to use the ordinary condenser of the lantern, the source of light having been moved further away from the lens than is usual; some photographs showing caustics, conical refraction, and diffraction; a stand for magnets, &c., when demonstrating the attraction and repulsion of poles; a stand for the suspension of objects for experiments on diamagnetism; a holder for X-ray tubes consisting of a spiral of wire fitting round the exhaustion tube of the bulb; an X-ray photograph taken by means of a Wimshurst machine; a model of Michelson's interference experiment; an arrangement to show subjective colours, in which a double lantern is arranged to give two partly over-lapping discs. A sheet of green glass is placed before one lantern, and the light of the other decreased till the illumination of the two discs is the same. The over-lap then appears white, while the remainder of the uncoloured disc appears red. Prof. Silvanus Thompson said he was surprised that "patent plate" was sufficiently good for Michelson's experiment. Had the author tried illuminating the discs, in his subjective effect experiment, for a very short interval, so that the eye should not have time to wander from one disc to the other? Mr. Griffith said that if you looked through a tube at one disc at a time, one appeared green and the other white. The Chairman said the point seemed to be, could you fatigue the eye simultaneously, or must it be successive? Prof. Silvanus Thompson said two common 1-inch microscope objectives were very suitable for projecting rings and brushes.—Mr. E. C. Baly read a paper on the passage of electricity through gases. In this paper, which is of a purely controversial nature, the author brings forward as arguments that electrical conduction in gases is not of an electrolytic nature the following: (1) That the sign of the change on the supposed gaseous ion is variable; (2) the initial resistance of a gas; (3) the invalidity of Ohm's law; (4) the permanence of the supposed gaseous electrolyte; (5) that every mixture of gases must equally be an electrolyte; (6) that the potential gradient in a vacuum-tube, when the current is passing, has been shown to be very uneven. It is very steep in the kathode glow, and is by no means a regular decline between the electrodes. Prof. Armstrong said it was difficult to know from what point of view the author had treated the question. The first part of the paper consisted almost entirely of a criticism of Prof. J. J. Thomson's theory and experiments. Prof. Thomson, however, is not the only observer who has dealt with this subject. The author's arguments seemed vitiated by the fact that he has looked upon the subject from one very narrow standpoint only, viz. the ionic hypothesis, and Lord Kelvin, for instance, does not believe in the truth of the ionic

hypothesis even in the case of liquids. Prof. Thomson has shown that the phenomena depend on the dryness of the gas, so that the conduction cannot depend on the gaseous molecule alone. In the case of conduction induced by a neighbouring discharge, this might be due to the expulsion of condensed vapour from the walls of the vessel. It would appear that in the dry state gases are not electrolytes. Mr. Enright said he thought it was not correct to say no work was done in electrolysis. Prof. Silvanus Thompson said that the pursuit of the analogy between the conductivity in gases and liquids was apt to lead one too far. Thus, if you compare the conduction in a mixture of H and Cl with electrolysis, your analogy will be a false one unless you import into the term electrolysis the idea of chemical separation as taking place in the solution. If a current separated a mixture of powdered zinc and sulphur, it could not be called a case of electrolysis. Prof. Armstrong said an experiment of Prof. Dewar's was very instructive. He had shown that if you cool the surface of a Crookes' tube the discharge stops. It was quite inconceivable that at these low pressures the gas became liquefied, so that this experiment seemed to show that conductivity depends on the presence of a vapourous electrolyte. Mr. Enright asked if Prof. Armstrong knew how the presence of an electrolyte assisted conduction. In a communication, Prof. J. J. Thomson said that, in the decomposition of steam by a spark, the fact that in the tube as a *whole* the amount of steam decomposed is greater than the amount of gases liberated in a voltameter in series, was no objection to the conductivity being electrolytic. The only condition imposed by the laws of electrolysis was that the excess of H or O at one terminal, and of O or H at the other, should correspond to the amount of electricity passing through the tube. Thus, suppose in a water voltameter a number of metal partitions are fixed so that the current has to pass across these plates. Then at each plate H will be given off on one side and O on the other, and by making the partitions sufficiently numerous, the total quantity of gases given off for the passage of a given current may be made as large as we please. The excess at the terminals would not be affected at all by these partitions. In the experiments made by Mr. Rutherford and himself (Prof. Thomson), they did not observe any polarisation when the conductivity was produced by Röntgen rays. With reference to Mr. Baly's objections to the electrolytic theory: (1) There is no reason to think that, under conditions other than in solution, the atom of hydrogen may not have a negative charge. (2) The electrolytic theory leads us to expect that it would require a finite electromotive force to send a discharge through a gas. Before such a discharge can take place, the molecules must be split up, and this requires an electric field of finite strength. (3) In the case of a gas, the electric field has to ionise the molecules, so that an increase in the strength of the field will not only (as in the case of a liquid electrolyte) increase the speed of the ions, but it will also increase their number, and thus the current will increase faster than the electromotive force. (4) The ion once used can again combine, and, since the ionisation is done by the electric field, it can be again split up and used again. If, however, the ionisation has been done by external sources—as, for example, by Röntgen rays—then we find that the conductivity decreases as the current passes. (5) There seems to be no reason on the electrolytic theory why, in a mixture of HCl and Cl, some of the current should not go through the chlorine. (6) A variable potential gradient would be produced if the ions moved with different velocities. Mr. Baly's process in the positive column appears to be the same as on the electrolytic theory minus the atomic charges. In a communication Prof. Schuster said: Mr. Baly criticises what he calls the electrolytic theory, but directs his arguments against a form of the theory which is, as far as the writer knows, advocated by no one. Mr. Baly appears not to have read the original papers in which the fundamental points of the theory, upheld by J. J. Thomson and the writer (Prof. Schuster), are explained. If he had done so, he could not have given, as an objection to the theory, that the conductivity of a gas increases with the E.M.F. The essential difference between a liquid and a gas is that in the liquid the number of ions is fixed by the chemical constitution of the liquid, while in a gas dissociation has, first of all, to be produced by the current itself, and hence the number of ions depends on the current. In the paper referred to by Mr. Baly, in which the fact that when a spark is passed through a gas the gas ceases to insulate for some distance round the spark is described, the explanation that this was due to a difficulty of passage of the electricity from the electrode into the gas was especially disclaimed. The explanation given being substantially the same as that now given by Mr. Baly. Mr. Baly asks what becomes of the ions that are set free? The answer, of course, is that they recombine. The view that stratifications are due to compound molecules, and do not probably occur in pure gases is not new. With reference to the author's statement that "measurements made by Wheatstone and J. J. Thomson prove that the electricity travels along the positive column from the anode to the kathode, and that its velocity is about half that of light," Prof. Thomson's results show that the break-down of the insulating power of air takes place in the manner described, but this does not show anything as to what happens when the discharge has reached the steady state. Mr. Baly is quite wrong in the excess charges he assigns to different parts of the vacuum tube. Experiments on the excess charges can count for nothing, unless they are done with continuous currents. Mr. Baly is further wrong in stating that the fall of potential is rapid in the glow. On the contrary it is very small in the glow, being very rapid in the dark space between the glow and the kathode. Mr. Baly adopts Prof. Thomson's view as to the formation of molecular chains, but in a form very difficult to accept. The whole foundation of Mr. Baly's theory is upset by his wrong assumptions as to the excess charges in different parts of the tube. The author, in his reply, said that on some points he had been misunderstood. He thought that the increase in conductivity could not be due to vapour driven off from the sides, for ultra-violet light also produced such an increase. If Röntgen rays produce ionisation, then there ought to be a reduction in the density of the gas.

Chemical Society, December 17, 1896.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—On the experimental methods employed in the examination of the products of starch-hydrolysis by diastase, by H. T. Brown, G. H. Morris, and J. H. Millar. From the results of a large amount of experimental work on starch-hydrolysis, the authors draw conclusions respecting the determination of solids from solution-density, the relation of $[\alpha]_j$ to $[\alpha]_D$, the determination of cupric reducing power, and discuss the limits of accuracy of the various methods.—On the specific rotation of maltose and of soluble starch, by H. T. Brown, G. H. Morris, and J. H. Millar. The specific rotation of 2 to 20 per cent. pure maltose solutions is constant, and at 15·5°, $[\alpha]_D = 137·93°$; soluble starch in 2·5 to 4·5 per cent. solutions has, at 15·5°, $[\alpha]_D = 202·0°$.—On the relation of the specific rotatory and cupric reducing powers of the products of starch-hydrolysis by diastase, by H. T. Brown, G. H. Morris, and J. H. Millar. The authors have established a definite relation between the specific rotation and the cupric reducing power of the products of starch-hydrolysis by diastase, which holds within very narrow limits.—The action of hydrogen peroxide and other oxidising agents on cobaltous salts in presence of alkali bicarbonates, by R. G. Durrant. Cobaltous solutions are turned green by hydrogen peroxide, hypochlorite, bromine, chlorine, or ozone in presence of alkali bicarbonates; the green colour is dependent on the production of a cobaltic salt and on the presence of carbonic anhydride.—Electrical conductivity of diethylammonium chloride in aqueous alcohol, by J. Walker and F. J. Hambly.—Formation of substituted oxytriazoles from phenylsemicarbazide, by G. Young and H. Annable. Substituted oxytriazoles are obtained when mixtures of phenylsemicarbazide with benzaldehyde, meta- or para-nitrobenzaldehyde, metatoluic aldehyde, terephthalic aldehyde, or cinnamic aldehyde are oxidised. — α-Bromocamphorsulpholactone, by C. Revis and F. S. Kipping. Under certain conditions an α-bromocamphorsulpholactone, $C_{10}H_{13}BrSO_4$, is formed during the sulphonation of α-bromocamphor.—Dimethylketohexamethylene, by F. S. Kipping.—The localisation of deliquescence in chloral hydrate crystals, by W. J. Pope. Great differences have been observed between the speeds of deliquescence of the various forms present on crystals of chloral hydrate.—Enantiomorphism, by W. J. Pope and F. S. Kipping. A preponderance of either right- or left-handed crystals of sodium chlorate is deposited on crystallising the material from aqueous solutions containing various optically active substances.

Linnean Society, December 17, 1896.—Dr. A. Günther, F.R.S., President, in the chair.—Messrs. James Green and J. H. Gardiner exhibited a series of sciagraphs of British batrachians and reptiles in which the details of the skeleton were very

sharply defined, and its relation to the external outline well shown. These sciagraphs, as well as those of a series of mollusca also exhibited, were taken with a Crookes' tube of the ordinary focus pattern actuated by a powerful induction-coil giving 8-inch sparks, and the prints in every case were made from untouched negatives. Prof. Howes offered some remarks on the series of batrachians and reptiles, and Mr. B. B. Woodward commented upon the details of structure which were made apparent in the sciagraphs of mollusca.—Mr. J. E. Harting exhibited a supposed hybrid between the common brown hare (*Lepus timidus*) and the Irish hare (*Lepus variabilis*) recently obtained in Carnarvonshire, where the latter species had been introduced in 1878. He compared the specimen in question with examples of both the above-named species, and contrasted their distinguishing peculiarities, pointing out the intermediate characters exhibited by the supposed hybrid. His remarks were criticised by the President, who thought that too much stress should not be laid upon external appearance and colour; that the question of hybridity should rather be determined by comparing the relative measurements of the leg-bones; and that the Irish hare should be compared in detail with the hare of Southern Europe (*L. meridionalis* or *mediterraneus*). Prof. Howes drew attention to Nathusius's observations upon the Peyer's patches of the leporines, and pointed to the necessity for examination of the viscera. Mr. Barrett Hamilton, who was present as a visitor, was inclined to regard the supposed hybrid as an example of the ordinary brown hare turning white in winter, hitherto unnoticed in this country. Mr. Thomas Christy inquired what position the so-called Belgian hare or leporine occupied in relation to the question of hybridity; and was answered that the popular notion of that animal being a hybrid between hare and rabbit was fallacious, since it was nothing more than an overgrown tame rabbit coloured like a hare.—Mr. B. B. Woodward gave a demonstration, illustrated with lantern-slides, of M. F. Bernard's researches into the development of the hinge of bivalve shells.—On behalf of Dr. A. J. Ewart, a paper was read in continuation of one previously communicated by him and entitled "Further Observations on Assimilatory Inhibition."—Mr. W. C. Worsdell gave the chief facts of a paper dealing with the development of the ovule of *Christisonia*, a genus of the Orobanchæ. Referring to Prof. Koch's detailed account of the development of the ovule of *Orobanche* he remarked that *Christisonia* as a parasitic plant was of such interest and differed so much in its vegetative structure from *Orobanche*, that it seemed to be worth while to record the facts of its embryological development. A brief description of the vegetative parts of the plant was then given. The author also described the development of the embryo-sac and the embryo. This was shown to follow essentially the same lines as in *Orobanche*. Finally, it was pointed out that in a great many plants the vegetative and the reproductive organs have not always, by any means, a parallel development. A striking instance of this was to be seen in *Christisonia*. The paper was criticised by Dr. D. H. Scott, who testified to the importance and interest of some of the facts established.—On behalf of Dr. L. O. Howard, entomologist to the U.S. Department of Agriculture, a paper was read on the Chalcididæ of the Island of Grenada, West Indies. This paper, communicated by Mr. F. D. Godman, F.R.S., dealt with the Chalcididæ collected by Mr. H. H. Smith, under the auspices of the British Association Committee for investigating the fauna and flora of the West Indian Islands. The collection consisted of from 600 to 700 specimens, and comprised six new genera and seventy-two new species, which were described. The geographical relationships of the group were discussed.

Geological Society, January 6.—Dr. Henry Hicks, F.R.S., President, in the chair.—On the structure of the skull of a Pliosaur, by C. W. Andrews. The paper deals with a specimen of the Plesiosaurian known as *Pliosaurus ferox*, Sauvage, obtained by Mr. A. N. Leeds from the Oxford clay near Peterborough, and now in the British Museum, and perhaps the finest Pliosaur skull known. The author gave a detailed description of the skull which formed the subject of the paper.—On the Pembroke earthquakes of August 1892, and November 1893, by Dr. Charles Davison. In the part of the paper referring to the origin of these earthquakes and their connection with faults, the author pointed out the possible value of the study of earthquakes in supplementing geological surveys. For more than fifty years prior to the earthquakes of 1892-93, there appear to have been no slips of importance along the fault-system of the area. After this prolonged interval of repose, the earlier movements took place along transverse (north and south) faults, and the later along longitudinal (east and west) ones. The three faults of the latter series, which the author connected with the disturbances, lie successively one to the north of the other, as if the abrupt displacement of a rock-mass over one thrust-plane impelled the advance of those immediately below. There can be little doubt that the fault-slips of 1892 affected the conditions of stress along the neighbouring transverse fault, so that the displacements along it occurred earlier than they might otherwise have done. In the discussion that followed the reading of the paper, the President said that the author's inquiries into the relationship between earthquakes and faults were of great interest. It was well known that the older rocks in Pembrokeshire have been much crushed and broken, and that thrust-faults of great magnitude occurred there. The Rev. J. F. Blake remarked upon the apparent absence of any signs of disturbance on the surface. If these earthquakes were due to slips, it was strange that none of them should yield this evidence. In the cases previously described by the author the principal evidence was the association with well-known faults, which might be lines of fresh dislocation; but in the present instance faults had to be hypothecated. Though, therefore, the speaker believed the theory to be the true one, the evidence for it appeared extremely weak.—Changes of level in the Bermuda Islands, by Prof. Ralph S. Tarr. The author gave a summary of previous writings bearing upon the geology of the Bermudas; but his own researches point to a rather more complicated series of changes than those which have been inferred by other writers. The formation of the "base-rock" or "beach-rock" occurred at some period which cannot be accurately ascertained at present, owing to the fragmentary nature of the included fossils. It may have been formed in Pleistocene or even late Tertiary times. After its formation it was converted into a dense limestone and then eroded, probably by subaerial agents, and finally attacked by the waves at an elevation of at least fifteen feet above present sea-level; during this stage it was covered by beach-deposits of pebbles and shells, which were accumulated in a period so recent that the contained fossils are of the same species as the organisms living in the neighbouring sea. Then followed an uplift, during which land-shells lived on the beach-deposits; but these were soon covered by blown sand—the principal accumulations of the islands, and the outline of the islands was perfected by the action of the winds. This was done at an elevation which was at one time certainly as much as 40 or 50 feet above present sea-level. The author adduced evidence of a depression since this accumulation, causing land to disappear and the outline of the area to become very irregular; and he proves that these changes cannot be accounted for solely by erosion, as some have maintained. There are indications that the land is at present quiescent. It appears, then, that most of the work of construction of the Bermudas has been done in recent times (see NATURE, vol. liv. p. 101.)

PARIS.

Academy of Sciences, January 18.—M. A. Chatin in the chair.—Researches on helium, by M. Berthelot. Helium, in contact with mercury and benzene, is slowly absorbed during the prolonged action of the silent discharge. After the sparking has proceeded for some time, a fine orange glow appears, sufficiently bright to be visible in daylight, which examined with the spectroscope under ordinary atmospheric pressure shows the characteristic lines of helium and mercury, together with some hydrocarbon bands. At a red heat the resinous compound breaks up, reforming helium.—Remarks on the specific heats of the elementary gases, and on their atomic constitution, by M. Berthelot. In a *résumé* of the results obtained for the specific heats of the elementary gases, it is shown that these fall into four groups, comprising the monatomic gases, helium, argon, and mercury, diatomic gases other than the halogens, the halogens, and tetratomic gases such as phosphorus and arsenic.—Methods for comparing, with the aid of the electric spark, the times of oscillations of two regulated pendulums of nearly equal period, by M. G. Lippmann. The two pendulums are twice photographed by the sparks from a jar discharge at a known interval of time, and the exact phase of oscillation of each pendulum measured micrometrically upon the negative. The accuracy of the method is much higher than the method of coincidences.—Classification of the chemical elements, by M. Lecoq de Boisbaudran.—M. Potain presented a series of radiographs on behalf of M. Serbanesco, of subjects affected by gout or chronic

rheumatism.—M. H. Lechappe gave further details of his apparatus for producing acetylene.—On an instrument for indicating ascending or descending movements in aerostats, by M. Aug. Coret.—New nebulæ discovered at the Observatory of Paris, by M. G. Bigourdan.—Observations of the Perrine comet (1896, December 8) made at the Toulouse Observatory with the Brunner equatorial, by M. F. Rossard.—On the first integrals of differential systems, by M. P. Painlevé.—On the poles of uniform functions of several independent variables, by M. Antonne.—On Taylor's series, by M. Eugène Fabry.—On the integration of the equation $d^2u/dt^2 = d^2u/dr^2 - u$, by M. Le Roux. The law of transparency of gases for the X-rays, by M. L. Benoist. Experiments on sulphurous acid, methyl chloride, and air show that the absorption is proportional to the density of the gas employed.—On the velocity of reduction of chromic acid by phosphorous acid, by M. G. Viard. The velocity of the reaction is given by $dx/dt = K(A - x)^4$, where x is the quantity of chromic acid reduced at the time t and A the initial quantity. —Action of hydrogen sulphide and hydrogen selenide upon phosphoryl trichloride, by M. A. Besson. With hydrogen sulphide in the cold the oxysulphide $P_2O_2S_3$ is formed in small quantity; at 100° the oxychlorosulphide $P_2O_2SCl_4$ is also found. The latter forms a colourless liquid distilling at 104° under a pressure of 10 mm. of mercury. Dry hydrogen selenide with excess of phosphoryl chloride gives HCl, P_2Se_5, and an oily liquid which gives with water metaphosphoric and hydrochloric acids.—On some salts and some derivatives of dinitro-orthocresol, by M. P. Cazeneuve. The potassium, ammonium, barium and calcium salts are described, also the acetyl and amido-derivatives. —Action of ethoxalyl chloride upon pseudocumene and mesitylene, by M. E. Bouveault. The reactions were carried out in presence of aluminium chloride, and follow the normal course.—On the diminution of the nitrogenous material in wheat from the department of the Nord, by M. Ballard.—On the influence of the section of the spinal medulla, in the cervical region, upon the repletion of the heart paralysed by electrification, by MM. J. L. Prevost and C. Radzikowski.—Influence of temperature and food upon the respiratory quotient of the moulds, by M. C. Gerber. The spores of *Sterigmatocystis nigra* were cultivated in Raulin's fluid, in which the only organic substance present was tartaric, malic, or citric acids, either alone or with saccharose in the proportions met with in fruit. The ratios of $CO_2 : O_2$ found were, 1·68 for citric acid, 1·76 for malic acid, and 2·47 for tartaric acid. The results are parallel to those obtained from fruits.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 28.

ROYAL SOCIETY, at 4.30.—On the Capacity and Residual Charge of Dielectrics as affected by Temperature and Time: Dr. J. Hopkinson, F.R.S., and E. Wilson.—On the Electrical Resistivity of Electrolytic Bismuth at Low Temperatures and in Magnetic Fields: Prof. Dewar, F.R.S., and Prof. Fleming, F.R.S.—On the Selective Conductivity exhibited by certain Polarising Substances: Prof. J. C. Bose.

ROYAL INSTITUTION, at 3.—Some Secrets of Crystals: Prof. H. A. Miers, F.R.S.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Electrical Interlocking, the Block, and Mechanical Signals on Railways: F. T. Hollins.

FRIDAY, JANUARY 29.

ROYAL INSTITUTION, at 9.—The Polarisation of the Electric Ray: Prof. J. C. Bose.

INSTITUTION OF CIVIL ENGINEERS, at 8.—An Experimental Investigation of the Efficiency of a Pelton Waterwheel: S. Henry Barraclough.

SUNDAY, JANUARY 31.

SUNDAY LECTURE SOCIETY, at 4.—Ancient and Modern Views of Fire: Dr. C. W. Kimmins.

MONDAY, FEBRUARY 1.

SOCIETY OF ARTS, at 8.—Material and Design in Pottery: Wm. Burton.

SOCIETY OF CHEMICAL INDUSTRY, at 8.

VICTORIA INSTITUTE, at 4.30.—Paper by Dr. J. D. Macdonald, F.R.S.

TUESDAY, FEBRUARY 2.

ROYAL INSTITUTION, at 3.—Animal Electricity: Prof. A. D. Waller, F.R.S.

ZOOLOGICAL SOCIETY, at 8.30.—General Account of his Expedition to the North Pacific: G. E. H. THE STUDY OF BACTERIOLOGY.

A Text-book of Bacteriology. By E. M. Crookshank, M.B. Fourth edition. Pp. xxx + 715. (London: H. K. Lewis, 1896.)

THE importance of bacteriology is undeniable; in fact, the study of the action of bacteria in health and in disease, inside and outside the animal body, has revealed so many new facts, it has already explained so many phenomena which formerly belonged to the realm of mystery and yet promises so much more, that we can easily understand why there was a danger, not even now totally removed, that, beguiled by this entrancing branch of science, pathologists would be led astray to regard bacteriology as the only portion of their subject worth taking up. We have at present a large number of "bacteriologists" in this country and abroad, many of whom are specialists who have entirely dissociated bacteriology from pathology, physiology, chemistry and botany. It requires comparatively little skill and study to be a "bacteriologist," and probably more incomplete and unsound work is published on bacteriology than in any other science. It is so easy to create a sensation with bacteria, especially where disease, or the prevention of disease, is concerned. Many bacteriologists, unfortunately, are quite satisfied in performing a few laboratory experiments without at the same time studying the disease itself, and they argue, only too often, from immature observations. They are ever criticising without being critical. In the study of disease, bacteriology cannot, and must not, be severed from pathology and clinical medicine or surgery. We insist on this, because recently an attempt has been made to have bacteriology recognised as a separate branch of the medical curriculum, with compulsory attendance and the inevitable examination at the end, without which there is no perfection. The principles of bacteriology must be, of course, taught with biology, pathology, clinical medicine and surgery, but the art and practice of bacteriology can only be taught by carefully-conducted courses extending over some weeks or months. If general compulsory classes were instituted, the student would acquire a smattering of practical bacteriology which is worse than useless, and this would encourage him in the idea that bacteriology is quite simple and mere child's play. Dr. Klein has warned us against the bacteriological cheap-jack.

"There seems to be an idea abroad, of which one hears only too often and sees its mischievous results continually, that for bacteriological and pathological studies and research all that is required is a platinum needle for inoculation, sterile nutrient gelatine in test-tubes (which can be easily bought by the dozen), a microscope with oil immersion, a microtome for sections (sections can be, of course, cut by any dexterous assistant), one or two aniline dyes (also easily bought ready made), and a book on bacteriology."

Thus writes Dr. Klein, and we agree with him that this is not bacteriological study; yet that might appear to be the ambition of those who advocate the introduction of compulsory courses in bacteriology. How many students who have been "signed up"—the signing up is an important factor in the scheme—would be competent to make a bacteriological diphtheria diagnosis? No more than would be competent to make a careful histological examination after a similar course in practical morbid histology. Let us leave the true science and art of bacteriology to the serious, and give them good laboratories, good instruction, and plenty of time and good books.

The student must derive much of his instruction from books, and, unfortunately, we possess but few good English books on bacteriology, and therefore we regret all the more that we cannot but express our disappointment with the new edition of Prof. Crookshank's work on bacteriology. We find that although the book is very bulky, that it contains but little information on points which require elucidation and discussion. Immunity is badly treated, and the process of immunity not discussed at all, and the principles of the antitoxins are touched upon in the most cursory manner, and there is no discussion whatever of the action of antitoxic or preventive serum and all the pathological questions involved. Although our knowledge of bacteriological chemistry is still very incomplete, we might have expected a full and critical account of what has been done. The chemistry of tetanus is not even brought up to date, but undue prominence is given by the author to his own researches on tuberculin, so that out of ten pages on the whole bacterial chemistry, three are devoted to his and Herroun's investigations, and the enzymes and ferments are passed over in eighteen short lines. The technical instructions are far too incomplete to be of any use, and had much better been left out, for practical bacteriology is best treated as a special subject. Coming to the pathological part of the book (Part ii.), we find that the whole subject is treated in 300 pages, of which about 100 pages treat of the diseases of animals. The utter lack of a sense of proportion is striking, and, as hinted above, the author's own work is always thrown into great relief. Thus, although actinomycosis occupies thirty-five pages, typhoid fever is rushed over in seven pages, if we make due allowances for the illustrations which fill five pages; cholera is skimmed in ten pages, with fifteen illustrations taking up about three pages; while to scarlet fever, with the notorious Hendon and the Wiltshire cows, twenty-two pages have been devoted, of which many are dreary reading full of controversial matter. Diphtheria has been deemed worthy of only five pages, tetanus of but two, and rabies of four. No important subject is clearly or carefully discussed, and the book is full of misleading and inaccurate statements. Thus we read, without any further explanation or criticism, on page 343: "Whether the typhoid bacillus is really peculiar to typhoid is much disputed. Bacilli very closely resembling it, if not actually identical, have been found under other conditions." The bacterium coli is not described, but passingly alluded to in a few lines which convey but little information, and the detection of the typhoid and colon bacillus in water is so incompletely explained as to be useless, and the import-

ance of the latter bacillus in analytical work is not considered at all. In fact, the whole chapter on typhoid fever, while omitting all that is wanted, contains nothing worth reading. Instead of reading page after page of diseases of deer, buffalo, boars, swine, fowls, horses, cows, ducks, grouse, mice, rats and other animals, the student would have preferred a serious discussion of the present position of the cholera or diphtheria question. The yeasts and moulds are also unsatisfactorily treated, and there again we cannot get away from cows, calves, fowls and mice, while man is of quite secondary importance. A few pages are devoted to the hæmatozoa, and here also the malaria parasite which occurs in man comes off badly, while the parasites of surra, of the common rat, and of fish are much more fully discussed. There is, of course, much regarding small-pox, cow-pox and other pox in the book, and also, for some reason or another, lengthy extracts from the final Report of the Vaccination Commission. All this is unsatisfactory reading, because the author does not write impartially on this matter.

In conclusion, we must say that the book, although well got-up, is not one which can be considered as worthy of English bacteriology. The best parts in the book are some of the illustrations of animal diseases; but even as a picture-book it is unsatisfactory, for some drawings are too diagrammatic and on an excessive scale. The absence of sound criticism, the lack of a just sense of proportion, and the want of a true appreciation of the problems of disease, and more especially of human disease, compel us to speak severely of the work, and to warn the student of bacteriology, who is needs surrounded by doubt and dogma, against placing his confidence in such a guide. A. A. KANTHACK.

PREHISTORIC MAN AND BEAST.

Prehistoric Man and Beast. By the Rev. H. N. Hutchinson, B.A., F.G.S. Pp. xxii + 298. (London: Smith, Elder, and Co., 1896.)

THE unscientific reader cannot fail to find much that is instructive in this work; it brings into a comparatively narrow compass information which could only otherwise be obtained by a wide course of reading, and it makes good its pretension to be fairly well abreast of the times.

There are many "good things" in it, generally distinguished by inverted commas. The author has the true instinct of a writer for the populace, and steadily pursues effect: to a striking passage he will succumb, even if it be a trifle meretricious, and it will be found inserted in its due place, with an apology if necessary. Witness the long extract giving "a rather fanciful picture" of palæolithic man" (pp. 34–36).

Naturally he has little sympathy with the technical details on which scientific results depend. "Every work dealing with prehistoric man contains," he says, "long and tedious descriptions of the famous skulls . . ." (p. 75). No doubt, yet we fancy there is more than one place in this work where a familiar knowledge of these details would have proved useful to the author. Again, on p. 22, we find "detailed evidence from sections in gravel-pits, &c. (*sic*), such as would be almost unintelligible, with the probable result that he would lay down the book at once." The detailed evidence was probably omitted in this case with judgment, but there are others in which some knowledge of "sections" would have greatly assisted the reader, and might possibly have saved the author from the following. "First of all stone was used. . . . *Hence* the stone age is the earliest." (The italics are ours.) On a question of fundamental importance, like the order of succession of the different prehistoric periods, the reader is likely to require evidence of a different nature to this.

The impatience for all that is technical savours of ingratitude when the author, speaking of those original investigators who have provided him with so much valuable material, remarks of them that they "have so obscured the romance by their 'dry-as-dust' descriptions and ponderous reports of their labours, that no ordinary reader would care to plod through a single chapter of their writings." Probably these writers were too solicitous about the truth to care much about the romance, which for the present may be left in the care of the author, who, let us hasten to add, is not always so censorious as these extracts might suggest; he praises the artist who has embellished his work with fancy pictures, and he praises Sir Henry Howorth, who generously returns the compliment.

It is a pity the book is not better illustrated; several sketchy drawings, spoken of as "restorations," occupy some ten plates, but of figures of real interest there are none. The ordinary reader would have welcomed reproductions of palæolithic drawings, and figures of ancient weapons; maps would have assisted him, and even geological sections might not have come amiss. Of the plates, some are worse than others. It will, perhaps, be fairest to choose the frontispiece for comment. It represents a palæolithic family receiving a call, at the photographed entrance of Wookey Hole, from three different kinds of wild beast. One, which we took to be a polar bear, we are informed is a machairodus; the next, a very stuffed-looking specimen, is a cave bear; and the third, a hyæna. The author recognises that a triple alliance of this kind is improbable; why, then, does he represent it? Because—and here we find the true popular writer—"it makes a more interesting picture," and "scientific accuracy should not be pushed too far." We let this pass, as well as the toy harpoon with which the cave man is defending his weeping wife and family, to ask if the author really supposes that palæolithic man is fairly represented by the tall, fair Caucasian with long straight nose, and orthognathous jaws, who does duty for him here.

It may be that this is, as the author claims for the illustrations, "a thoroughly artistic and vivid picture," though it is more than doubtful whether it "would well bear reproduction on a larger scale"; but we are in cordial agreement with him when he remarks that it is not a scientific, "mere scientific" diagram, and—we should prefer the diagram.

We are not quite sure whether the author has any really clear ideas of the bodily aspect of the people he wishes to portray. In speaking of the stage of culture of

palæolithic man, he makes use of Mr. Tylor's comparison with the aborigines of Tasmania; but on p. 36 we find the following: "In speaking of the probable mental and moral condition of man in the older stone age, we have, for want of further material, compared him with the aborigines of Australia, Tasmania, and New Zealand." Next time the author visits the British Museum, he will, perhaps, take a glance at the weapons and other implements of the Maoris that are exhibited there, and reconsider the evidence on which he regards these people as useful for purposes of comparison with men of the palæolithic age.

There is a great deal of foolish writing—there is no other term for it—in Chapter iv. headed "The Myth of the Great Ice-Sheet." The author concludes a tiresome tirade by admitting an ice-sheet, formed of confluent glaciers, which covered the greater part of the British Isles; he calls it a "modest local or British ice-sheet." With this conclusion in view, we might well have been spared the vapourings on "superstition," "bugbears," "myths," "nightmares," and the like—terms culled apparently from Sir Henry Howorth's vocabulary—as well as the somewhat spiteful gossip about Agassiz and Schimper. More modesty might have been expected from a popular writer; we shall not imitate Mr. Hutchinson's style, and say a mere popular writer—it would be rude—in discussing the views of some of the great geologists of the past. To speak of Ramsay, Agassiz, and Croll as having "gone mad over ice," as prostrating before it "not only their bodies, but their minds," and as having been beyond the reach of reason, is not becoming: still worse is the expression that Croll misled the public. Croll requires no defence from us, and we make no further comment.

The author appears as a reconciler of Genesis and science, with a somewhat inadequate acquaintance with Babylonian writings; the same deficiency appears in the ten pages devoted to the question of the origin of the zodiacal signs. He was warned of the doubtful nature of Mr. Peck's theory by Mr. Flinders Petrie, but introduces it with the usual plea—it may be wrong, but it is "interesting." There is an extensive literature on the origin of the zodiacal signs, and the probabilities all point to Babylonia as their birthplace.

As for the literary style of the book, it is well enough so long as the author keeps to digests, summaries, and simple descriptions; but where he gives us something of his own, the result is less pleasing. We could well have dispensed with several feeble witticisms, a parade of puerile suggestions, and a good deal of sentiment. As an instance of the author's undiluted style, we quote the following:—

"How delighted must Mr. Ruskin and all true followers of our great teacher and prophet be to learn that, after all, we shall not have to give up our fairies! And what an anti-climax must such a result appear to those hard, unsentimental scientific workers and thinkers who were wont to consider fairy tales as nothing but pure 'stuff and nonsense'! It must be somewhat humiliating to such—if there be any left—to reflect that they must no longer dare to despise fairies, but are compelled, in the sacred name of Science (with a *very* big S), to pay homage to them!"

W. J. SOLLAS.

OUR BOOK SHELF.

Getting Gold: a Practical Treatise for Prospectors, Miners, and Students. By J. C. F. Johnson, F.G.S., Member of the Aust. Inst. of Mining Engineers, Pp. xii + 204. (London: Charles Griffin and Co., Ltd., 1897.)

IN this book will be found much practical information on the mining and subsequent treatment of gold ores, particularly useful to the prospector setting out for Australia. It has often been said that the practical man does not write books, but there is here a complete refutation of the calumny. There are chapters on the "genesiology" of gold, which are hardly of practical value, on the treatment of ores by various processes, and on company formation. A useful section, too, is devoted to prospecting, in which the various difficulties of finding gold are clearly set forth. "Where it is, there it is," the author quotes, "and where it is, generally, there I ain't." The best part of the book, however, is undoubtedly under the heading of the "Rules of Thumb." Here the practical man shows what he can do. The recipes given are absolutely encyclopædic, and all more or less to the point. We are told how to make fire, how to find water, how to purify it and carry it, how to copy correspondence, to cross a flooded stream, and to build a house. One is lost in admiration at the wealth of knowledge displayed, and the mixture of "cuteness" and simplicity in the remarks.

The tables at the end of the book are less happy. A dozen or more mistakes occur in a short table of fusing and boiling points, and the elementary algebra seems unnecessary in the present state of primary education. Nevertheless, though not without faults, the book will be most useful to prospectors who have not been through a course of study at a School of Mines

Photo-Trichromatic Printing. By C. G. Zander. (Raithby, Lawrence, and Co., Ltd., 1896.)

THIS book is a model of neatness and printing, and harmonises well with the subject of which it treats. The author has not attempted an elaborate text-book on the optical sciences of chromatics and spectroscopy, but states in a straightforward and clear manner the outlines of the causes of colour phenomena and the effects of pigmentary mixtures and combinations. A perusal of the fifty pages shows that Mr. Zander has adopted a very happy arrangement for the sequence of the matter dealt with, making the book easy reading for even those who are not very familiar with the subject.

The first of the four parts into which the book is divided treats of chromatics and, more briefly, spectroscopy, the reader being introduced to the three fundamental colour sensations. In Part ii. pigment mixtures are discussed, and many a useful hint may be gathered here by those who wish to know the why and the wherefore of common every-day manipulations. The explanatory diagrams showing the absorption of two typical pigments and those of the resulting mixtures are all that could be desired. A useful *aide-mémoire* is the chromatic clock-dial, which is an ingenious idea for helping those who work with colours to remember which are the contrast or complementary colours, and how saddened colours or tints may be produced.

Three-colour work, or the production of any colour by the combination of the three primary colour sensations, is treated of in the third part.

The concluding section is devoted to the important question of photochromic printing inks, the author pointing out the chief essential qualities that they must possess for successful work.

We may say, in conclusion, that printers and artists have in these few pages a useful handy guide, which will give them an insight into the art of successful photochromic three-colour printing.

The Earth and its Story; a First Book of Geology. By Prof. Angelo Heilprin. Pp. 267. (Boston: Silver, Burdett, and Co. London: Gay and Bird, 1896.)

THIS is a most attractive little book of geology. It presents very clearly the general facts concerning the formation, structure and development of the earth; and notwithstanding its popular character, it contains a large amount of the more detailed information required by the elementary student of the subject.

Prof. Heilprin begins with the decay of rocks, and then describes the appearances and origins of the commoner rocks. The subsequent subject-matter follows this order: formation of mountains and valleys, snow and glaciers, underground waters, relation of the sea to the land, the earth in its interior, volcanoes, earthquakes, coral and coral islands, fossils, physiognomy of the land-surface, common and useful metals and minerals, building stones, soils and fertilisers, and common rock-forming minerals. It will be seen from this outline that the book is comprehensive enough to meet the needs of the average student; its form is also popular enough to attract a large number of lay readers.

The volume is most liberally illustrated, and the illustrations possess the immense advantage of being reproductions from photographs. There are sixty-four full-page plates, most of them containing two pictures, and all of them exhibiting striking objects or phenomena. We do not know of a better illustrated introductory text-book of geology than the one which Prof. Heilprin has given us. The book is more suitable for use in American colleges and high schools than in our own; but there ought to be a demand for it on this side of the Atlantic.

The Climate of Bournemouth in Relation to Disease, especially Phthisis. By A. Kinsey-Morgan, M.D., &c. Pp. 51. (Bristol: John Wright and Co., 1897.)

THE important part which climate plays in the etiology and cure of lung diseases is well recognised. In this essay Dr. Kinsey-Morgan shows the advantages which Bournemouth offers to consumptive patients, or to persons suffering from any form of chest disease. He differs from writers on continental health-resorts and sanatoria, inasmuch as he points out how hygiene and medical influences must supplement climatic conditions, and insists that wholesome sanitary surroundings are more important points to be considered than particular thermal or mineral waters.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Carbon in Bright-Line Stars.

IN an article "On the Question of Carbon in Bright-line Stars," in your issue of January 28, Prof. Lockyer makes the following statement in reference to our paper "On Wolf and Rayet's Bright-line Stars in Cygnus."

"As a result of their work, they make the following statement: 'Our observations appear to us, however, to be conclusive on the main subject of our inquiry, namely, that the bright blue band in the three Wolf-Rayet stars in Cygnus, and in DM 37° 3821, is not coincident with THE BLUE BAND OF THE BUNSEN FLAME.' The capitals are mine. It will be seen how carefully Vogel, in the case of comets, and myself, in the case of stars, had pointed out that it was not a question of the Bunsen flame!"

I am glad that the last words of the quotation from our paper were put in capitals, as they emphasise the assertions which we had to meet, namely, Prof. Lockyer's assertions in an article in NATURE (vol. xlviii. p 344):—

"In the Bakerian Lecture for 1888, I gave a complete discussion of the spectra of bright-lined stars, as far as the observations went, and the conclusion arrived at was that they were nothing more than swarms of meteorites, a little more condensed than those we know as nebulæ. The main argument in favour of this conclusion was the presence of the bright fluting of carbon which extends from 468 to 474."

Now, this bright fluting of carbon is that known as the blue band of the Bunsen flame. The variations of the position of maximum of brightness which may take place within it, were fully discussed in our paper, and do not affect the range of wave-length. Even the anomalous band photographed from a vacuum tube at South Kensington gives little help, for it is scarcely necessary to repeat that in two stars the bright band lies outside this region; and in the other, though the maximum falls near the more refrangible limit of the blue carbon band, a large part of it falls outside the carbon band.

But Prof. Lockyer himself puts beyond doubt that by his words, "the bright fluting of carbon," he did mean what we call "the blue band of the Bunsen flame," for he goes on to say (NATURE, *loc. cit.*):—

"Direct comparisons of the spectrum of all three stars in Cygnus, with the flame of a spirit-lamp, have been made by Mr. Fowler, and SHOWED AN ABSOLUTE COINCIDENCE OF THE BRIGHT BAND IN THE STARS WITH THE BLUE BAND OF THE CARBON SEEN IN THE FLAME. It was found quite easy to get the narrow spectrum of the star superposed upon the broader spectrum of the flame, so that both could be observed simultaneously."

The capitals are mine. Now, bright bands having an absolute coincidence with the blue band of carbon in the flame, could be no other than the blue band seen in the Bunsen flame. This was the assertion which we had to meet; an assertion stated to be supported by direct comparisons of the stars with a carbon flame. It was, therefore, necessary for us to make it clear that this assertion was incorrect; and to say, in words which could not be mistaken, that "the bright blue band in the three stars is not coincident with the blue band of the Bunsen flame."

I am not aware that Prof. Lockyer has withdrawn the observations made at South Kensington. They are certainly remarkable, indeed unique, in the annals of spectroscopic research, for Mr. Fowler saw the blue band of his flame to have ABSOLUTE COINCIDENCE with three different star bands, which, all three, differ from each other in wave-length.

If the blue band, differing in position in each star, were the blue carbon band, as Prof. Lockyer asserts it to be, we should certainly expect to find in the spectra of the stars indications of the other bands of the carbon spectrum, especially of the bright green band and of the orange band. Now, there *are* bright bands in these parts of the spectra of the stars: but we state in our paper, as the result of a very careful direct comparison of these bright places in the star-spectra with a carbon flame, that there is no connection whatever between the bright star bands and the carbon flutings. This important result has been fully confirmed by the recent measures of these bright star bands taken by Prof. Campbell. His measures of the bright places in the star spectra, *which are well seen upon the continuous spectrum*, show with certainty that they have not their origin in carbon. Prof. Lockyer says that "Prof. Campbell does not discuss the origins of the lines and bands which he has measured."

Prof. Campbell's words are:—

"It is now a question of identifying the lines and bands with the lines of known elements, and of assigning to these stars their true place along with other types of celestial objects. A most perplexing question! The hydrogen lines, Hα, Hβ, Hγ, Hδ, are present, but the other lines do not admit of certain identification. Prominent iron and other lines may coincide with a few of the star lines, and the line at 4480 suggests a magnesium origin; but there are not enough points of identity with well-known artificial or stellar spectra to enable us to draw any safe conclusions" (*Astronomy and Astro-Physics*, 1894, p. 472).

As Prof. Vogel's name is prominently brought forward in Prof. Lockyer's article, it may be well to say that Prof. Vogel has nowhere identified the blue bands in the Wolf-Rayet stars, of which he was the first to determine the wave-lengths with any approach to precision, with the blue radiation of carbon.

I should perhaps point out that, though Prof. Campbell does suggest magnesium, he is careful not to make any suggestion as to the presence of carbon. WILLIAM HUGGINS.

Upper Tulse Hill, S.W., January 30.

Symbols of Applied Algebra.

UNFORTUNATELY Mr. C. S. Jackson (p. 293) does not appear to believe that I mean what I say, nor does he definitely apprehend what I mean. It is possible, however, that he represents some other teachers, and, therefore, I must regretfully occupy your space with the elementary statements: (1) that absolute measure has nothing to do with "standard substances"; directly a standard substance is introduced the "measure" becomes relative; (2) that specific gravities are expressible in tons per cubic yard (weight or mass being understood in accordance with context and subject-matter), or in grammes per cubic inch, or even in dynes or poundals per cubic metre; and (3) that to consider a density as a mere number is erroneous.

January 31. OLIVER J. LODGE.

On Mass.

DESPITE the extraordinary letter of Mr. C. S. Jackson, which appears in your issue of December 31, 1896, I must say that if there is a term which teachers of rational mechanics should retain and emphasise, it is the term *mass*. Mass denotes the quantity of matter, or the amount of stuff, in a given body. It is a definite and invariable quantity, whether you have the body at latitude 0° or at latitude 90°: whether you conceive it transferred to the surface of Jupiter, or to the outermost ring of Saturn.

On the other hand, the weight of the said body is a variable quantity, being measurably greater in a high than in a low latitude. At the earth's centre, it vanishes; on the moon, it would be less than here in New York; whilst on Jupiter, it would be considerably greater.

The inevitable conclusion is that scientifically the *mass* of a given body is of more importance than such a variable quantity as its *weight*.

This holds even commercially, for when we buy a pound of sugar we are more concerned with the quantity of the saccharine material that we get than with its weight. The weight is taken, in any given place, as a convenient measure of the mass.

Mr. Jackson's equation

$$P/Q = f/a$$

is misleading; it is true only when the forces P and Q act on *equal masses*. To write such an equation without the above statement, is merely begging the whole question at issue.

It is to be hoped that teachers of rational mechanics will ever insist on the different ideas connoted by the terms *Mass* and *Weight*. M. F. O'REILLY.

Manhattan College, New York City, January 13.

Dynamical Units.

IF Prof. Perry's reply to my letter (on p. 126) is summed up in the charge that I think of "stuff" when I ought to be thinking of inertia, then the issue between us should reduce to very minute dimensions. It is, perhaps, unfortunate that in English the term mass may signify either "quantity of matter" or the inertia of that matter, but hardly so unfortunate as the fact that weight may denote either a quantity of matter or a force, an ambiguity to which we are all prone, though Prof. Perry makes light of it; for a definite amount of matter implies, at least, a definite amount of inertia, but not a definite weight, in the sense of force If Prof. Perry thinks that with himself the word mass means simply inertia, then, substituting at the bottom of p. 49 in the current volume, I find that he says: "My unit of inertia is the *inertia* [the italics are mine] to which unit force gives an acceleration of 1 foot per second per second." I am free to confess that I cannot dissociate the conception of inertia from the idea of matter; but here we have abstraction indeed.

The main points to which I confined my remarks were the observation that with British standards the poundal is unique among units of force, and the showing that the alternative system of units advocated by Prof. Perry is artificial and inconvenient. Even if he makes such verbal alterations in my letter as may suit his craving for rigorous expression, the objections to his proposals will still hold. But I do not know for certain what alterations he demands. In the case of a student who is commencing the study of dynamics by observing the effect of forces applied to bodies moving smoothly on the flat, would he tell him at the outset that it is not a number of pounds of iron or other stuff that he is moving about, though he may think so, but an amount *m* of inertia? Surely he would not. Or is it that he objects to my statement that his system involves the conception of one piece of matter (the standard pound) whose weight (under conditions) is the unit of force, and also of another lump of matter of 32·18 lbs. whose inertia is the unit of inertia? Well, if he says that no such conception presents itself to him I will not insist. I am not familiar with his psychological processes, but such images arose in my mind on reading his exposition of the system, and I think the same would (and ought to) occur in the case of a student on first trying to understand it. And it is for the beginner that Prof. Perry is so solicitous: an advanced student may be left to choose his own system, and will get on in spite of all systems.

In seeking to justify his preference, Prof. Perry, dexterously using the figure paraleipsis, extracts such support as he can get from existing legal definitions of the pound. We have had our law-abiding instincts appealed to in this connection before; but the law is a broken reed to rely on. The legal standard pound was originally established almost entirely with a view to facilitate the accurate weighing of Prof. Perry's conventional or metaphysical ideas—in other words, quantities of stuff of various kinds. Its environment did not signify, as its weight, in the sense for which modern physicists try to reserve the term, was quite a secondary matter. The standard pound was adopted for the sake of something which it and all its true copies, of whatever material they may be made, possess, or appear to possess, in themselves; and this thing they possess, or are associated with to the same extent wherever they may exist in the known universe: and it is not their weight, in the modern sense. It is their mass, in the sense of, or as measured by, their quantity of inertia. Prof. Perry is welcome to whatever comfort he can obtain from the wording of Weights and Measures Acts.

However, we have the thing—the standard pound. No one denies that its weight, when it is placed in vacuo near London, furnishes us with an excellent practical unit of force. But this is not good enough to secure the banishment of the poundal and the dynamical system associated with it. I do not quite gather where Prof. Perry himself considers the "huggermugger" comes in with regard to this unit; but if I understand his letter aright, something perilously near to this appears to have crept in among his observations on the subject.

In his letter (NATURE, vol. lv. p. 176) he affects to ignore the fact that the standard pound really furnishes us with a standard *something* that is constant—its inertia. He uses such phrases as "Assuming . . . that the weight and inertia of a certain body measured under the same circumstances at the same place are always the same"; and again: "Now here are your standards" (*i.e.* of weight and inertia) "in one piece of metal and its environment, and in your instruments." How ingenious is the suggestion that its inertia suffers from the same incurable disease that afflicts its weight, viz. that it is a function not of the body only, but also of its more or less unknown and uncontrollable environment. If it should ever be shown, as he seems to think may occur, that for a given body its inertia—the ratio of force to acceleration produced—is not to be regarded as an absolute constant, then not only the poundal, but a good many more of our dynamical ideas will have to be thoroughly overhauled.

Furthermore, he cannot mean what he appears to say, that he really considers the weight of a body, its attraction by and for the earth, to be the most fundamental property of matter, though from the stress he lays on the importance of his system one might almost suppose that it is so, and, moreover, that it is the weight at London which possesses this distinction. If he means that he regards the gravitational field of force associated with every particle of matter (ether-stress, if you will) as the most fundamental property of matter, I understand him, while not quite agreeing with him. Still, he can found a mechanical system on that basis, free from the objections applying to his present system; but it will have no 32·18, and I am afraid practical men will not receive it with gratitude.

As emphatically pointed out by Prof. Lodge, the interest of the question is pre-eminently educational. Prof. Perry agrees that to an expert, so far as his own personal work is concerned, the units he works in are generally of no great consequence. Such a one can use, say, the Birmingham wire-gauge or the Baumé hydrometer with much more facility than an ordinary person could use more rational devices. And so far as actual

practical calculations go, Prof. Perry, in getting out in foot-pounds the energy of rotation of a fly-wheel, or in making a conversion into horse-power from C.G.S. units, merely does his division by g (arithmetically or symbolically) at an early stage, where a "poundalist" would probably divide at the end. But with the elementary student it is different; a misconception at the start may stick to him for years unnoticed. Perhaps an occasional bath among all sorts of difficulties in which he is told to sink or swim, such as Prof. Perry advocates, may have a stimulating effect. But let us consider. Prof. Perry's main complaint was that so many are overwhelmed by the poundal. (Oddly enough, he does not seem to mind the dyne, which is on all-fours with it; in fact he has nothing to say against the work of the B.A. Units Committee, beyond a grumble at the fact that they acquiesced in the formula $4\pi\rho^2$ as representing the surface of a sphere.) Now, for instance, will a student not be puzzled as to the reason why this new system should bear to the English standards a relation so utterly unlike that which the C.G.S. system bears to the French standards? And it seems to me that there must be students who might manage to keep afloat in presence of the poundal to whom Prof. Perry's definition, that "the unit force is that which would give to a body of 32·18 times the inertia of the standard object kept in London an acceleration of 1 foot per second per second"—invented out of pure kindness for them—may prove a very millstone round their necks. And they will be no better off if he raises the talismanic number to 32·19, as apparently he would now do.

May I conclude by suggesting to Prof. Perry, by way of a small return for the many useful things which I have learnt from him during the past twenty years and more, that an appreciative toleration of rule-of-thumb methods is one thing, but it is another thing to glorify and perpetuate them.

Ashurst Wood, January 12. M. J. JACKSON.

Durham Science Degrees.

I AM surprised to see the letter of your anonymous correspondent "X." in your issue of January 28.

All the six gentlemen referred to, hold important positions on the teaching staff of this college.

They were recommended by the Council of the college to the Senate of the University as deserving such a degree as would make them members of the Convocation of the University.

"X." insinuates that these gentlemen had no qualification for this honour.

The truth is, that one of them is M.Sc. of Victoria University, three of them are B.Sc. of Scotch Universities; the remaining two are the Senior Lecturers in their respective departments, where they have taught graduates of the University for twelve and thirteen years respectively. HENRY PALIN GURNEY.

The Durham College of Science, Newcastle-upon-Tyne, January 29.

PHOTOGRAPHY IN COLOURS.

THE announcement has been made during the past week of the discovery of a true process of photography in colours. It is too early now to discuss the matter in its many interesting bearings, since the process so far remains more or less secret, but the following communications will indicate how the question at present stands.

The first is a *communiqué* received from Sir H. Trueman Wood, the Secretary of the Society of Arts.

I am anxious to make, through the medium of the Society of Arts *Journal*, at all events a preliminary announcement of a very remarkable process for producing photographs in colours which was brought to my notice the other day. To say that it enables photographs to be produced in natural colours would not, perhaps, be precisely true, since colouring media are employed; but the result of the process is a photograph in colours of nature—a faithful reproduction in colour of the object photographed—and so, for all practical purposes, it may be said that the long-sought object of photographic research, photography in colour, has actually been obtained.

The inventor is M. Villedieu-Chassagne, of Paris, who has developed a process originally suggested by Dr. Adrian Dansac, and the following is his method:—(It must be premised that he keeps secret, at all events for the present, the nature of the four solutions he employs.) A negative is taken on a gelatine plate prepared by treatment with one of his solutions. This is developed and fixed in the ordinary manner. It shows no trace of colour. From it a print is taken on glass or paper, the plate or paper being specially prepared by treatment with the same solution. The transparency or the paper print in no way differs, to all appearance, from an ordinary positive, and shows no trace of colour by transmitted or by reflected light. It is then washed over successively with three coloured solutions, blue, green, and red, and it takes up the appropriate colours in appropriate parts, these three colours giving, by their various combinations, all varieties of hue. How it is that this power of selective absorption is given to the components of the photographic image (principally, of course, metallic silver) is, it appears to me, the interesting question connected with the process. The action is certainly previously unknown, and it will, as certainly, repay scientific investigation.

As I declined to be convinced by mere inspection of the finished results, M. Chassagne was good enough to demonstrate the whole process for my benefit, and by the kindness of Prof. Thomson, of King's College, the demonstration was allowed to take place in the laboratory of King's College on two mornings last week. Prof. Thomson and Mr. Herbert Jackson, of King's College, were present on both occasions, and Captain Abney on the second. I must not speak for those gentlemen, but I believe they were as much impressed as I was myself by the remarkable nature of the process and its results.

That such results should be obtained by such a process seemed *à priori* in the highest degree improbable, but obtained they certainly were.

The photographs taken by ourselves were poor, the light (on the morning of Wednesday, 20th) being extremely bad. Nevertheless, the positives (made by one of ourselves on the following day) showed with perfect distinctness, when treated as above described, the colours of a bunch of flowers I had bought at Covent Garden, on my way to King's College, and of various other test objects.

Our own experiments were confined to gelatine films, but M. Chassagne treated with complete success some paper positives he had brought from Paris. These looked like ordinary silver prints toned with gold, but I omitted to ask about the toning.

Further experiments and independent investigation (for which M. Chassagne has kindly promised me the materials) will, no doubt, throw further light on the nature of the process; but I cannot believe that any investigation will throw doubt on its genuine character, for it was carried out under test conditions last week, the sole reservation being the nature of the materials employed.

I hope that a fuller account of the method may shortly be presented to the Society in the form of a paper; but in the meantime it appeared to me that members of the Society would be interested by having placed before them the first information about so remarkable and promising an invention. H. TRUEMAN WOOD.

Captain Abney, who was present at the experiments referred to above, writes as follows:—

The process of colour photography, which I had the pleasure of seeing demonstrated at King's College some ten days ago, through the kindness of Sir H. T. Wood, is a very remarkable one. I went as a sceptic.

The process may be described in a very few lines. In the first place a negative is taken on a gelatine plate, which has been specially prepared. The plate is developed and fixed in the ordinary way, and the image appears of the same character as if taken on a good density-giving plate. A transparency (a positive) is next taken on a similar plate from this negative, or a silver print made on specially prepared albumenised paper, on either of which the colour process is worked. The colouring is of a very simple nature. There are three dyes—a crimson-red, a grass-green, and a very good blue, all in solution, and mixed with some other ingredients besides water. There is also what we may call a mordant in the shape of a colourless liquid containing, I should say, albumen and salt.

This last liquid is brushed copiously over the face of the positive (or the silver print), and the blue dye applied a little at a time. If the light be good (and it was stated that the colouring must take place in good daylight), the blue dye rapidly takes hold of those portions of the surface which represent in monochrome what are blues in the original. For instance, a china vase will take the blue tint, and the face or hands a faint amount of the same colour. The green dye is applied in the same manner, and the greens in the original make their appearance in the positive, and so with the red. Finally the print or positive presents a picture in colours, underlying which is the dark brown silver image. It appears as if the image took up selectively these three colours; but why it takes them up, it is hard to see. I have by me a portrait done in the manner described, and the negative has evidently been retouched with the pencil. It is difficult to understand why a pencil mark should be the cause of selective absorption of the colours, or that a special plate should be necessary. That the success of the process does not depend upon the inventor's manipulation is quite evident, for negatives were taken by Sir H. T. Wood, quite independently of him, but of course on prepared plates given him for the purpose, and from these he made positives. These last, when treated with the colouring matter, gave the correct colours of the original. Still I am somewhat sceptical—I believe it is my failing to be so—and I shall not be satisfied till I get the plates that have been promised me by the inventor (M. Chassagne), and taken negatives of certain test objects which will be unknown to the inventor. If he can reproduce their colours it will have to be without any reference to the amounts of silver which ordinarily indicate the colour in the original, for in the negatives sent every colour will be represented by approximately an equal density. Some few years ago a powder process was seen by Mr. C. V. Boys, in which three coloured powders selectively adhered to the surface of paper. The paper was prepared with some glutinous substance and bichromate of potash, and which remained more or less tucky according to the amount of exposure to light it received. These three powders, a red, a green, and a blue, I believe, if applied in a certain order, adhered to the print, and gave approximately correct results of colour, though no special negative was required. Whether this new process now described depends on any similar grounds, it is hard to say at present.

The point that strikes me in the latest process is that it is only from a specially prepared negative that a print suitable for colouring can be made. Were it the negative which took up the colour, one might understand the matter better. To me at present the process as stated is a mystery; but if it does all that it is claimed for it, it must be a great success, and the theory of it will have to be investigated in a thoroughly scientific manner. At present the details are a secret; but I am given to understand that the seal of secrecy will be withdrawn before long, as a patent is applied for. We shall then be able to ascertain on what principles the process is worked.

W. DE W. ABNEY.

BRITISH ASSOCIATION MEETING IN TORONTO.

I.—LOCAL ARRANGEMENTS.

THE various special Local Committees, organised to make preparations for the British Association meeting, to take place in Toronto this year, have now, after a year's work, to report very satisfactory progress in the arrangements for the occasion. In the case of some of the Committees, their work may be considered as finished. The special Committee on Finance, for instance, has secured promises of financial aid to the extent of 5700*l.* from the Governments of the Dominion of Canada and the Province of Ontario, and from the Toronto City Council. This sum will, it is believed, be fully sufficient for all the expenses of the meeting, which, owing to the special circumstances of the occasion, must be larger than those of any meeting in Great Britain.

The Committee on Rooms also has, for the present, finished its labours. According to its report, which has been adopted by the Local Executive Committee, the reception room, general offices, and the rooms for the sectional meetings are all to be in the various lecture-rooms and laboratories of the University of Toronto and of the School of Practical Science. As the buildings of the University and School are in the centre of the city, and within less than five minutes' walk from the electric car line which communicates with all parts of the city, the selection offers every convenience in the way of conveyance. The rooms selected are large and well adapted for the purposes assigned, and all are within a short distance of each other. Sections A and H (Mathematical and Physical Science and Anthropology) will occupy lecture-rooms in the main building of the University, Sections D, I and K (Zoology, Physiology and Botany) are allotted rooms in the Biological building, Section B (Chemistry) will be placed in the Chemical building, Section E (Geography) in the general reading-room of the University library, while Sections C, F and G (Geology, Economics and Mechanical Science) are to be given large rooms in the University Y.M.C.A. building, Students' Union building, and in the School of Practical Science respectively. The only building to be used by the Association, and not situated on the University grounds, is Massey Hall, in which will be delivered the President's address and the evening lectures. It is capable of seating 4000 persons, and has splendid acoustic properties.

One of the conversaziones will be held in the main building of the University; the other will, it is expected, be given in the new buildings of the Provincial Legislature. A number of gentlemen have kindly offered to give garden parties, while the Faculties of Trinity College and Victoria College have arranged to hold receptions. The various Clubs in the city will be open to the members of the Association.

The arrangements for conveyance are not yet completed, but the concessions already made by the Steamship and Railway Companies may be announced. The Canadian Steamship Companies, the Allan, Dominion and Beaver Lines (Liverpool and Londonderry to Quebec and Montreal) have granted to members of the Association considerable reductions in rates for single and return tickets, and the Anchor Line (Glasgow and New York) offer reasonable rates for single or return first-class tickets. A copy of a circular giving information in regard to Atlantic steamship rates will be sent to each member of the Association in a few weeks. It may be well to note that berths are to be applied for early in the season; for the choice, if made late in June or July, may not be a large one. The Canadian Pacific and Grand Trunk Railway Companies have decided that round

return) trip first-class tickets over their lines may be obtained by members for the single fare, and that for single trips between points on their lines in Canada east of Port Arthur (on Lake Superior) only half rates (¾*d.* per mile) will be charged. The Canadian Pacific Railway Company will also give free tickets for trips over the branch roads of the main line in the North-west and British Columbia, and will arrange a special excursion to the Pacific Coast, to take place after the meeting, for a number of members and guests of the British Association.

Additional excursions to other parts of Canada have been provided for. Niagara Falls may be reached from Toronto in three hours by the large fine steamers of the Ontario Navigation Company, which ascend the Niagara River to a point connected with the Falls by two electric car lines. This excursion may be made on any day, and an opportunity will be offered to visitors to spend the time from Saturday to Monday at the Falls. It is expected also that members will have the privilege of inspecting the means employed of "harnessing Niagara." Another excursion, to the beautiful Muskoka Lake region, Ontario's summer resort, four hours (by rail) distant from Toronto, is offered. The members may leave Toronto at 3 p.m. on Saturday, August 21, and return early Monday morning. There will be, on an afternoon during the meeting, an excursion to the Ontario Agricultural College and Farm, in the neighbourhood of the town of Guelph. The Committee on Excursions is providing also for a number of special excursions to Nova Scotia, Kingston, and the Thousand Islands, Montreal, Ottawa, the Upper Lakes, to cover from five days to three weeks. The town authorities of Sudbury are preparing for an excursion of members to that district, in which are to be found the richest nickel mines in the world. Parties interested in mining also will, by special excursions, visit the Western Ontario gold mines, and the gold mines of British Columbia, which at present are attracting much attention.

The special Committee on Publication is preparing a hand-book of the Dominion, which will give an account of its resources, and of its geological, climatic and other features. It is expected that copies of this hand-book will be ready for distribution amongst the members before they start for Canada.

The Local Committee has decided to invite a number of distinguished continental (European) scientific men, and it is believed that not a few of these will accept the invitation. A very large number, also, of prominent American scientific men have expressed their intention of attending the meeting. The American Association for the Advancement of Science meets on August 9, at Detroit, 240 miles from Toronto, in order to allow its members to be present at the meeting of the British Association. The Society of American Naturalists, the American Psychological Association—both very important and strong organisations—have accepted for their members invitations to join the British Association and attend its meetings. It is confidently believed that the Toronto meeting will have very largely an international character, and that the numbers in attendance will be very great.

The people of the Dominion in general, and of Toronto especially, are determined that the coming meeting shall not fall one whit in interest behind any meeting held in the British Isles. As the time approaches, the interest in it daily increases. Canadians realise also that it is a rare opportunity to show what their country is in grandeur, in extent, and in resources; and they will leave nothing undone which will make the meeting a success from every point of view. It must also be said that for the British man of science the occasion is the opportunity of a life-time.

A. B. MACALLUM.

NEW FOREIGN MEMBERS OF THE ROYAL SOCIETY.

WE are able to give this week portraits of the recently elected foreign members of the Royal Society—Giovanni V. Schiaparelli, the Astronomer and Director of the Royal Brera Observatory in Milan; Prof. Albert Heim, the geologist, Professor of Geology in the Hochschule and Polytechnische Schule of Zürich; Prof. Gabriel Lippmann, Professor of Physics in the University of Paris, and a Director of the Physics Laboratory of the Sorbonne École des Hautes Études; and Prof. Gösta Mittag-Leffler, Professor of Pure Mathematics in the Hochschule, and Director of the Mathematische Seminar at Stockholm.

Prof. Giovanni V. Schiaparelli is best known for his researches in meteoric and cometary astronomy, and for his acute observation of planetary characteristics. He is the author of numerous papers in the Milan *Rendiconti*, the *Journal de Physique*, the *Annalen der Physik*, in the *Comptes rendus*, in *Les Mondes*, and elsewhere. In 1867 his papers, "Intorno al corso ed all' origine probabile delle stelle meteoriche," "Sur la relation qui existe entre les comètes et les étoiles filantes" (*Astronomische Nachrichten*), and "Sur l'origine des étoiles filantes de Novembre" appeared. Later came "Sul calcolo di Laplace intorno alla probabilità delle orbite cometarie iperboliche," and "Nuovi fatti e nuove teorie sulla repulsione nelle comete"; and more recently "Osservazioni astronomiche e fisiche sull' asse di rotazione e sulla topografia del Pianeta Marte," "Observations de la tache polaire australe de Mars pendant l'opposition de 1879," and a number of other papers on this planet. His observations of Mercury and Venus, which led him to conclude that the period of rotation of each of these planets is the same as that of revolution around the sun, are also noteworthy contributions to astronomy.

Prof. Heim is well-known for his work in reference to glacial action and to mountain structure. Among his more important published works are his "Handbuch der Gletscher Kunde," published in 1884, and his "Untersuchungen über den Mechanismus der Gebirgsbildung," besides a number of occasional contributions to scientific literature, including various papers on Glaciers, printed in the *Annales Phys. Chem.*, in the *Schweizer. Naturf. Gesellschaft Verhandlungen*, &c., in the Zurich *Vierteljahrschrift*, &c., also "Les tremblements de terre et leur étude scientifique," in the *Archives Sci. Phys. Nat.*

Prof. Lippmann is well known to men of science by his important observations respecting electro-capillary phenomena, leading to his invention of the capillary electrometer; and by his recent researches upon colour photography, in which he has attained the optical solution of a problem at one time considered insoluble. By photographic processes he has produced brilliant pictures, not only of the spectrum and simple coloured subjects, but also of landscapes and figures. Among his other published works are numerous contributions to the *Journal de Physique*, the *Revue Scientifique*, the *Comptes rendus*, &c., on the relations between electrical and capillary phenomena, on units of electrical force, on experimental determinations of the ohm, and kindred subjects.

Prof. Gösta Mittag-Leffler, whose name is familiar as the founder and editor of the *Acta Mathematica*, is distinguished for his researches in the theory of functions and in other regions of pure mathematics. His published papers are numerous, and have appeared principally in the Stockholm *Ofversigt*, in the *Acta Societae Scientiarum*, Helsingfors, and in the Paris *Comptes rendus*. Among the more important may be mentioned a series of papers in the *Ofversigt*, "Om den analytiska framstellningen af funktioner utaf rationel karakter," "Funktionsteoretiska Studier" in the *Helsingfors Acta*. "Sur la theorie des fonctions uniformes d'une variable" in the Paris *Comptes rendus*, &c.

GIOVANNI SCHIAPARELLI (*Milan*).

ALBERT HEIM (*Zürich*).

GABRIEL LIPPMANN (*Paris*).

GOSTA MITTAG-LEFFLER (*Stockholm*).

THE NEW FOREIGN MEMBERS OF THE ROYAL SOCIETY.

SCIENCE AND MORALS.

FOR some little time past the intellectual air of Paris has been enlivened by a controversy between men like M. Berthelot, M. Lavisse, M. Anatole France, and M. Gaston Paris, as supporters of the gospel that the disinterested search for truth is a guide to morality, and a reactionary party which has, with surprising dialectics, attempted to sustain a plea of the "failure of science." From the *Times* of Friday last, we learn that on Thursday the reception at the Academy of M. Gaston Paris, the successor of M. Renan as the head of the Collége de France, and one of those who have done most in philological studies to maintain the renown of French science, was the occasion of a signal demonstration against the reactionary, unscientific spirit.

M. Gaston Paris is reported to have said :—

"It will be understood that science, which every day enhances, enlarges, and renders more precise our conception of the world, and which transforms, at the same time more and more effectively, the conditions of our existence by submitting to our laws the matter which was crushing us, inspires an enthusiasm almost religious in those enamoured of it. No one had this cult more deeply rooted in his soul than M. Pasteur. No one claimed more insistently for science the honour and the place to which it has a right, or became more indignant with the stupid misunderstanding which refuses to it the means of action of which it stands in need. In a brief piece of writing, entitled 'Le Budget de la Science,' published in 1868, he adjured his fellow-citizens to take more interest in 'those sacred abodes known under the expressive name of laboratories. Ask that they should be multiplied and adorned. They are the temples of the future. It is there that humanity becomes greater and stronger and better.' He had the joy and the supreme honour to see rise under his invocation, owing to the munificence of the entire nation, the most magnificent of these temples of the future. There he reposes to-day in his glory, and about his tomb has been formed, like an order of the new times, a militant, truly spiritual band which fights under his banner to extend his conquests, and which will remain faithful to the motto which he gave it while working unremittingly—'Pour la science, la patrie, et l'humanité.'"

But, continued M. Gaston Paris, science had more than one method, and he recalled the memorable sitting some twenty years ago when Renan received Pasteur into the Academy, and these two great men exchanged words never to be forgotten, Pasteur proclaiming the grandeur of the experimental method as the only infallible instrument of discovery, and Renan claiming for historic and philosophic criticism the share due to it in the conquest and defence of truth.

M. Gaston Paris went on to say :—

"This science of which Pasteur was the priest and the prophet, this science to which we owe so many marvels, is accused of not having kept certain promises, some of which have been made by representations that it disowns, and others of which can only be realised with time. A special reproach made against it is that it is not yet ready to provide humanity with the moral direction of which it stands in need. Science might reply that it does not extend its empire so far, and that other forces which it does not deny are destined to do in the field of sentiment and action what it does in the field of knowledge. But it can, and rightly, as Pasteur affirmed, lay claim to its large share in this moral direction itself. If, unfortunately, it is not certain that in pointing out in the social instinct the true basis of morals, it assures to this instinct predominance over selfish instincts, it is certain that in drawing tighter the bands that bind men together, in undermining the barriers which still separate them, it renders easier and indicates as nearer at hand the civilisation of the world as a whole. . . .

"Science, in the circles where it is honoured and comprehended, does not restrict to men of science themselves the moral benefit which it confers. It diffuses in wider circles the love of truth and the habit of seeking it without bias, of recognising it only by unalloyed proofs, and of submitting docilely to it. I think that no loftier or more fruitful virtue can be inculcated in a nation."

THE PHOTOGRAPHIC OBSERVATION OF CLOUDS.

IT is a commonplace to say that the phenomena that present themselves most frequently are also those that are least observed with accuracy and intelligence. The ever-changing aspect of our sky, and the screen of vapour covering that adds charm to landscape and variety to scenery, present numberless opportunities for study and critical examination, but they have long waited for adequate description and representation. It was not till the beginning of this century that any special nomenclature was invented to describe the alterations that take place from hour to hour, and the very slight additions that have been made to this special vocabulary since Luke Howard proposed the three well-known terms of description, show the neglect from which this department of meteorology has suffered. These terms, too, though they have become the common property of all nations, are limited to description, and suggest nothing of the physical causes that determine the appearances he so happily described. Indeed, meteorology in his day was not in a position to push the inquiry with hope of success, and it may even still be urged that the explanations offered to account for some of the recognised types of cloud formation are largely speculative. This neglect of a very charming study has been brought about, not only by the fact that clouds are of ordinary every-day occurrence, and therefore not worth noting, but students of practical meteorology have perhaps too much considered that barometer and thermometer readings are the one thing needful, and have looked to the preparation of a weather chart as a veritable sheet-anchor to maintain and support the position of the science. For hitherto the general character of cloud observation among even painstaking meteorologists has been lamentably insufficient. A rough personal estimate of the percentage of area covered by cloud is frequently all that is given, with very little reference to the distance from the zenith at which these clouds are seen, and consequently neglecting the effects of foreshortening. Altitude, density, direction of motion, character of formation have all been regarded as of small consequence, but it is to be hoped that an epoch of more useful and more exact observation is dawning and possibly we may run into the other extreme, now that attention is being called to the subject, and devote too much time to the consideration of these fleeting appearances, and accumulate more results than can be effectively studied.

It might have been anticipated that artists, who maintain so constantly that they reproduce precisely what they see, would have given us pictures of clouds in some degree approaching to accuracy, and have made the discussion of their forms and characteristics easier for men of science. But as a rule the study of these specialists has scarcely been more exact or painstaking than that of the ordinary public, who, from the causes hinted at, are especially unfitted to apply that wholesome criticism which might have resulted in promoting more accurate representation. We believe there is a case on record in which a painter represented a rainbow with the colours reversed. This was unwise, because a rainbow being a rarer phenomenon than ordinary clouds, it has attracted more attention from the public, and the error was noticed. But faults as egregious too often accompany artistic production of clouds, and pass without censure or remark. Painters may make rain fall from a thin strip of cloud, or from impossible cumulus, and escape without ridicule. But these are freaks it is no longer safe to indulge in.

The artist, too, who paints by sunlight and without the aid of brushes and colours, is often as glaringly incorrect as his more respected and ambitious brother. We have

heard in the past, we know not with what truth, of artfully-placed pieces of cotton-wool on the printing frame, and of other devices, which, by judicious handling, have been made to give an appearance remotely resembling that of natural clouds, and that competent judges have been deceived by these means. A great authority on photographic reproduction has laid it down as a rule that the same "sky" should not be printed on more than one picture; and that such advice should be considered necessary, shows the length to which ingenious fraud has been carried in this matter. And yet it might be thought that if accurate reproduction of cloud-forms was attempted anywhere, it would be found in photographs of landscape. Some of the reasons for its non-appearance, very well known to practical photographers, have recently been discussed in NATURE (No. 1367), and valuable suggestions made to overcome these difficulties. The photographer does not always wish to reproduce the actual state of the sky at the time his photograph was taken. He thinks he can produce a better artistic effect by employing clouds of his own manufacture; but, apart from this, there is an inherent difficulty in obtaining a satisfactory negative of the lighter forms of cirrus and cirro-cumulus. The blue colour of the sky has practically the same chemical action on the sensitised plate as that exercised by the white colour of these fleecy clouds, and the contrast on which the photographer relies for his effects is wanting. The rules of procedure there given have resulted in some excellent representations, of which specimens will be found in the recently issued International Cloud Atlas, a work that may possibly revolutionise our methods of cloud observation.

Although the processes of photography have been sadly abused, it is undoubtedly to the employment of the camera, scientifically used, that we must look for the best results. Every day sees these results accumulating, and, as a necessary consequence, the introduction of greater uniformity in the classification and nomenclature of cloud observations. Also, greater and more frequent use suggests numerous devices to the expert, by which he may win more trustworthy pictures of the lighter forms.

It is now possible to reproduce very light cirro-cumulus clouds, and though some of the delicacy of the original may be lost in the method of printing, sufficient detail remains to enable one to judge of the success that attends the processes that Prof. Riggenbach, of Basle, and others have successfully advocated. Prof. Riggenbach avails himself of the fact that, while the light from a cloud is only slightly polarised, the light from the blue sky is much more so, especially at points which are 90° from the sun. By employing a Nicol prism, therefore, the skylight may be darkened to a very considerable extent, while the fleecy filaments of the cloud will come out with greater sharpness and distinctness. A dark mirror may be employed instead of the Nicol prism, and a still simpler means is to use the still surface of a lake as a polarising mirror. When clouds have an altitude of about 37°, and differ in azimuth from the sun by about 90°, they can be photographed in this way with ease and truthfulness. Another method which secures admirable results, though it may not be at the disposal of every one, is to photograph the clouds directly, at a considerable elevation above the sea-level. Here, on the top of a mountain summit, the sky appears much darker than in the plain, caused probably by the absence of scattered light from dust particles, which are more numerous in the lower strata. The observer, too, has the additional advantage of lessening the distance between himself and the cloud

FIG. 1.—Cloud, photographed at an altitude of 2500 m.

photographed. Our first illustration (Fig. 1) shows the appearance of a cumulus cloud as seen from the top of the Santis Mount at a height of 2500 m. At this elevation a yellow glass placed in front of the lens is all the protection needed. The other picture (Fig. 2) shows that excellent results can be obtained at the sea-level with proper chemical treatment of the negative. These pictures were taken by Prof. Riggenbach, who kindly permits their reproduction, and both appeal to us by their evident fidelity.[1]

But it must not for a moment be supposed that the object sought is to secure pretty pictures, or even accurate pictures. In clouds we have portions of the atmosphere which, from natural causes, have become temporarily visible, and as clouds exist at practically all heights above the surface, their study must reveal to us something of the behaviour of the atmosphere at otherwise inaccessible points. Wind and currents of the atmosphere, to say nothing of the vertical displacement of large masses of the air, must betray themselves by the motion of the clouds, if the cloud movements are interpreted correctly; and the connection between wind and "weather" is so intimate, that the possibility of predicting the one depends in a large measure upon our knowledge of the other. The definite knowledge of the height of a cloud, and the means of accurately determining its distance becomes, therefore, a problem of the highest importance in meteorology, and it is one in which, fortunately, photography can render efficient assistance. If two simultaneous instantaneous photographs of the same cloud be secured at stations, distant possibly half a mile apart from each other, the height of the cloud can be determined by trigonometry. This process has been carried out systematically at various observatories. Two observers, a suitable distance apart, and in connection with each other by telephone, select a cloud by arrangement to which each points a camera, and the simultaneous exposure is effected by one of the operators releasing the shutters of both cameras at the same instant. Considerable impetus has been given to inquiries of this nature, not only by the possibility of greater accuracy being secured to the photographs when improved methods have been employed, but by the action of the International Meteorological Congress, who, mainly at the instance of M. Hildebrandsson, have arranged a scheme by which observers in all countries are invited to take part in a common investigation, which has for its aim the determination of the altitudes and the motions of different kinds of cloud. Theodolites can also be used advantageously in this work. This scheme, which was originally contemplated to be in force for one year from May 1896, will soon be completed, and will add materially to our knowledge of the motions of the clouds, and, by inference, of the motion of the atmosphere. The observation of the behaviour of a kite, when at a considerable elevation it plays in some measure the part of a cloud, can be made, in skilful hands, to reveal the direction of atmospheric currents at generally inaccessible heights. This method, which is being actively prosecuted under the auspices of the Weather Meteorological Bureau of America, has the advantage that the height of the kite is always approximately known, and is free from eddies and currents likely to be produced by irregularities on the earth's surface. Moreover, if the object of cloud observation be not so much the methods of formation as the study of air currents, kite-flying is likely to afford on

FIG. 2.—Clouds, photographed at low-level station

[1] M. Plumandon, of the Puy de Dôme Observatory, has also sent us some excellent specimens of his work, but the photographs arrived too late to be reproduced.

some grounds more accurate information, because a cloud produced under peculiar circumstances, such as a mountain-cloud cap, for example, may appear stationary under even a strong current of wind.

As an instance of another welcome result that attends cloud photography, we might refer to the confirmation it affords of recent mathematical investigation concerning the origin of cloud. Herr von Helmholtz has demonstrated that when one current of air passes over another of different density or different temperature, waves must arise at the two surfaces in contact, similar to those produced on water under the action of wind. These atmospheric waves are, however, of quite different dimensions to the ordinary water-wave. The distance between two contiguous crests in the atmosphere is incomparably larger than the similar wave-length in water, and, indeed, may be reckoned in kilometres. Air waves become visible when sufficient moisture is present, and the wave-crests can be seen in the form of clouds presenting the appearance of parallel billows, and for which the name of "Wogen wolken" has been suggested. In this form they have been repeatedly photographed. A well-known example that has been frequently reproduced, has been taken from the Lick Observatory. From other elevated stations, where the conditions have been favourable, pictures of these nebulous waves have been secured, proving the justness of the views held by Helmholtz. A mass of alto-stratus cloud will frequently show that a subsequent stage of the process of formation has been reached. When the regular parallel billows produced between strata of air have met other currents having different velocities and densities, the result is to break up the regular form into more or less lozenge-shaped pieces, of which the appearance is very familiar, and the methods and terms of description equally numerous. To do away with these vague terms of description, and to substitute others which may have closer reference to the physical structure, and perhaps indicate something of the relative heights of clouds, is one result for which we may look from the more satisfactory application of photography to cloud phenomena.

NOTES.

AT last Thursday's meeting of the Royal Society, the following words of congratulation were addressed to Lord Lister, the President, by Sir John Evans:—"As Treasurer and as one of the older of the Fellows of this Society, I beg to offer you on their behalf and my own our most hearty congratulations on the high yet well-merited honour that Her Majesty has been graciously pleased to confer upon you by elevating you to the Peerage. We have great satisfaction in feeling that, while this distinction is a fitting recognition of the value of your life-long labours in invoking the aid of science to the relief of suffering humanity, it comes at a time when this Society has the honour and pleasure of looking up to you as its President. If anything could add to that satisfaction, it is the fact that with your new dignity you are still able to retain the name of Lister, for the name of Lister, among the inhabitants of all the civilised countries of the globe, is 'familiar in their mouths as household words.'"

WE understand that Lady Prestwich is collecting material for a biography of the late Sir Joseph Prestwich, and will be grateful to friends if they will forward to her any letters they possess, addressing to Shoreham, near Sevenoaks. These will be at once copied and carefully returned.

A GERMAN antarctic meteorological station will be established shortly in Victoria Land, under the direction of Dr. Rudolph Mewes. The station will be in connection with the German South Polar expedition, and will have for its object the determination of meteorological conditions during the antarctic winter.

DR. NANSEN will lecture upon his Arctic expedition, at the Royal Albert Hall, on Monday next, at 9 p.m. A Reuter dispatch from Christiania says that during his visit to Great Britain Dr. Nansen will deliver forty-seven lectures. The explorer will then go to Germany, and at the end of March will be present at a great demonstration of the Geographical Society in Berlin, organised in his honour. On leaving Berlin Dr. Nansen will go to St. Petersburg, where he will have an official reception. Subsequently he will visit Paris in response to an intimation conveyed to him by the French Consul-General in Christiania, and will again be the object of an official reception. Early in October next, accompanied by his wife, Dr. Nansen will leave for New York, in order to deliver a course of fifty lectures in various cities of the United States.

IT may be remembered that a sum of money was raised, and placed in the hands of the Royal Society, to found a scholarship in honour of Joule. The Council of the Society resolved that the scholarship should be awarded alternately in England and in other countries, for the purpose of encouraging young investigators to walk in the steps of Joule. In accordance with this decision, the Royal Society asked the Paris Academy of Sciences to nominate a candidate for the award this year; and we learn from *La Nature*, that the Committee appointed to consider the claims of young French physicists have selected M. Jean Perrin, of the École normale, for that distinction.

DR. CLEGHORN, Sanitary Commissioner for Bombay, is the special Indian medical expert selected by the Indian Government to attend the International Conference, to be held in Venice on February 10, to consider what means Europe should take to control the bubonic plague, should that disease advance towards the confines of Europe. Dr. Thorne Thorne, principal medical officer of health to the Local Government Board, has accepted the appointment of British Technical Commissioner at the same Conference.

THE honour in which Pasteur's name is held throughout the world is shown by the fact, announced in the *British Medical Journal*, that the subscriptions in France and other countries for a statue to the great investigator now amounts to more than £10,000. M. Paul Dubois has been selected as the sculptor, and the site for the statue will probably be the space between the Rue de Médicis and the Luxembourg Gardens. More than £20,000 has already been spent in the erection of statues of Pasteur in various parts of France. As an instance of the high regard in which he is held outside that country, it may be mentioned that the municipality of Mexico has given the name of Pasteur to the gardens situated in front of the National School of Medicine in that city.

WHEN the regulations for the muzzling of dogs in London and adjoining counties came into force at the beginning of last year, it was pointed out in these columns that rabies could not be stamped out by leaving local authorities to deal with it. The welfare of adjacent districts is so closely involved, that to place in the hands of different County Councils the power to enforce regulations for preventing the spread of disease, which knows not county boundaries, is absurd on the face of it. The only way to effectually cope with the evil is for some central authority, as, for instance, the Board of Agriculture, to compel joint action on the part of authorities having control over the areas where rabies exist. A muzzling and registration order so enforced for a couple of years would, in all probability, bring about the disappearance of the disease from our island. The report, just issued, of the Departmental Committee of the Board of Agriculture, appointed at the end of last April, "to inquire also and report upon the working of the laws relating to dogs," bears out this opinion. Statistics are quoted to support the con-

clusion that the powers of muzzling as exercised since 1882 by local authorities are inadequate to eradicate rabies, and only result in temporary and local checks to its spread. It is pointed out that the Board of Agriculture should have regard to the country as a whole, and should impose muzzling over considerable areas, irrespective of the boundaries of boroughs and counties; that the Board should impose it, in fact, where it is really required, and leave the rest of the country free. With the extirpation of rabies the necessity of muzzling will have disappeared, but the Committee think it expedient that more efficient means should be devised for the due licensing of dogs, and for their subsequent regulation. As to the question of a compulsory system of registration of dogs, it is considered that the matter should be entrusted to the Board of Agriculture, not to local authorities. With regard to the importation of dogs, the Committee consider that, without resorting to the extreme remedy of absolute prohibition, it would be possible for the Board of Agriculture to arrange, in concert with the Customs authorities, a system under which a sufficiently effective supervision may be secured over dogs landed in this country. In Norway, Denmark, and Sweden a system of quarantine is insisted upon; and in New South Wales, we believe, a dog has to undergo about six months' quarantine before it is allowed to enter the country, a heavy fine being imposed on the person causing this quarantine to be averted. If something of this kind were enforced in our own country, rabies would be as little known here as it is there. The first thing to be done, is to stamp out the disease by combined action; it would then be a comparatively easy matter to prevent its re-introduction.

AN eminent surgeon, who rendered distinguished services to the medical profession and to humanity, has just passed away in the person of Sir Spencer Wells. In 1882–83 Sir Spencer Wells was President of the Royal College of Surgeons. He received the honorary degree of M.D. from several universities, and was a member of many learned societies at home and abroad.

DR. AGAMENNONE, who has studied so successfully the earthquakes of Turkey and the south-east of Europe during the last two years, has not renewed his engagement with the Ottoman Government, and will shortly resume his work in Italy in connection with the Central Office of Meteorology and Geodynamics at Rome.

THE President of the Board of Trade has appointed a Committee, consisting of Major F. A. Marindin, R.E., C.M.G. (chairman), Earl Russell, Sir Douglas Galton, K.C.B., F.R.S., Sir Charles Scotter, and Dr. John Scott Haldane, to inquire into the existing system of ventilation of tunnels on the Metropolitan Railway, and report whether any, and, if so, what steps can be taken to add to its efficiency in the interest of the public.

ON Friday, January 22, Prof. Guido Cora delivered an address, at the Alpine Club in Turin, on Dr. Nansen's Polar expedition of 1893–96. This was, we understand, the first special meeting of a scientific society held to discuss the results obtained by Nansen in his recent journey.

PROF. W. E. AYRTON, F.R.S., will lecture at the Imperial Institute, next Monday, on "Sixty Years of Submarine Telegraphy." The lecture will be illustrated with historical and modern apparatus showing the development of submarine telegraphy, oil paintings of the chief pioneers, lantern slides showing the operations of making and laying a cable, experiments on the velocity of electric waves in a submarine cable, and in other ways will be made interesting. Mr. W. H. Preece, C.B., F.R.S., will occupy the chair.

ON Thursday next (February 11), Dr. J. W. Gregory will deliver the first of a course of three lectures at the Royal Institution, on "The Problems of Arctic Geology"; and on Saturday (February 13) Mr. Walter Frewen Lord will begin a course of three lectures on "The Growth of the Mediterranean Route to the East." The Friday evening discourse (on February 12) will be delivered by Prof. John Milne, F.R.S., his subject being "Recent Advances in Seismology." That on February 19 will be by Mr. G. Johnstone Stoney, who will lecture on "The Approaching Return of the Great Swarm of November Meteors."

THE twenty-fourth annual dinner of the old students of the Royal School of Mines was held on Tuesday, January 26, at the Criterion Restaurant, and was attended by over 120 Associates and others who have been connected with the School. The chair was taken by Dr. T. K. Rose, of the Royal Mint, and he was supported by a number of past and present Professors at the School of Mines and Royal College of Science. In proposing the toast of prosperity to the mining and metallurgical industries, Dr. Rose dealt with the great advances in gold production and the influence of the cyanide process, and then referred to the recent progress of investigation of the inner nature of metals. The recently published register of old students was also mentioned as an event of the year.

DR. ARTHUR WILLEY, who worked out the later development of Amphioxus when he was a pupil of Prof. Ray Lankester at University College, London, has just made a most important discovery. He has succeeded in obtaining the ripe eggs of the Pearly Nautilus, and is now at work on the development of that most interesting animal. Two and a half years ago Dr. Willey gave up a teaching post in Columbia College, New York, and accepted the Balfour Studentship of the University of Cambridge, in order to proceed to the coast of New Guinea and neighbouring islands in quest of the embryological history of the pearly nautilus. He has had great numbers of live nautilus, but, in spite of all efforts, had, till December 5 last, failed to obtain the eggs. Specimens which he was keeping in a large cage, sunk in the sea at a suitable spot in the Loyalty Islands, were found by him on that day to have spawned. Dr. Willey's indomitable perseverance and devotion to his task have thus been at last crowned by success. Dr. Willey has been assisted in his arduous and dangerous enterprise—amongst the savage people of those remote islands—by grants of money from the Government Grant Fund administered by the Royal Society.

THE first number of vol. vi. of the *Atti dei Lincei* contains no less than three papers on phenomena associated with Röntgen rays. In the first of these, Prof. Villari considers the relation between the dissociation produced in gases by these rays, in virtue of which such gases discharge electrified bodies, and the molecular association produced by the transformation of oxygen into ozone by means of the electric spark. In one series of experiments a current of air was first traversed by Röntgen rays and then allowed to pass through an ozonator before falling on a charged electroscope, and it was found that the ozonator deprived the air of its power of discharging the electroscope. Prof. Villari's paper is illustrated by figures showing the patterns obtained when the surface of the ozonator is sprinkled with a mixture of sulphur and red lead.

THE second paper is a note, by Prof. A. Róiti, on the apparent deflection of Röntgen rays behind opaque obstacles. Prof. Róiti has obtained closely analogous effects with ordinary light by observing the shadows of opaque objects made by an incandescent gas-burner. A note, by Prof. Stefano Capranica, forms a sequel to his previous investigations on the biological action of the rays. Moles were inoculated with the virus of enteritis, and were subjected to the action of the rays. The symptoms were identical with those shown by animals protected from the rays, and the moles died in either case in about the same time; showing that the rays possess no influence, either for good or bad, on animals infested by pathogenic bacilli.

A. DE HEMPTINNE publishes, in the December number of the *Zeitschrift für physikalische Chemie*, an account of an attempt to detect some action of the Röntgen rays on chemical processes. His results confirm those already obtained by Prof. Dixon and Mr. H. B. Baker, and others. The conductivity of electrolytes in aqueous solution, the hydrolysis of etherial salts by acids, and the combination of chlorine with hydrogen and carbon monoxide were studied; no effect could be detected. Solutions of silver nitrate in alcohol, and of mercuric chloride and ammonium oxalate in water, which are decomposed by light, gave only minute and uncertain traces of change when exposed to the Röntgen rays.

A WRITER in the current number of *Blackwood's Magazine* gives a prospective account of a trans-Pacific cable. It is interesting to find that the coral reefs, which, in the opinion of the late Sir John Pender, constituted the chief difficulty in the way of the scheme, are not a serious obstacle. Modern soundings have shown the reefs to lie in well-defined groups, and it happens that the ocean expanses between them contain wide and uniform depressions, particularly suitable for a cable. The article points out that the most favoured route is from Vancouver to Fanning Island; Fanning Island to Fiji; Fiji to Norfolk Island; and from Norfolk Island in two sections—one to New Zealand, and the other to Australia. Fanning Island is of coral formation, and is about ten miles long by four miles wide; it is the nearest British possession to Vancouver on the Australian route. The article gives an account of the history of the Pacific cable scheme, and states its financial aspect.

THE current number of the *Comptes rendus* contains a description of an absolute electrometer intended for measuring small electromotive forces (about 1 volt), designed by MM. Pérot et Fabry. The instrument consists of an attracted disc electrometer, in which the necessary sensitiveness is obtained by greatly reducing the distance between the plates. The attracting disc consists of the plane end of a glass cylinder about 6 cm. in diameter and 1 cm. high, this height being large compared with the distance betweeen the two discs. The attracted disc consists of a thin circular disc of glass about 7 cm. in diameter, and which is virtually an infinite plane. These discs are lightly silvered, and their parallelism adjusted, and their distance measured by being traversed normally by a beam of monochromatic light, which forms interference bands between the light which has passed directly through the thin silver coating and that which has been reflected an even number of times at the silvered surfaces. The electrical attraction is measured by comparing the deformation produced in three springs, which carry the movable disc by the electrical forces, with that produced by a known weight when placed on the movable disc. The authors have obtained 0·0048467 as the mean value of the electromotive force of a Clark cell at 0° in electrostatic measure, and, taking the electromotive force in electromagnetic units as $1·4535 \times 10^8$, the value of v, the ratio of the units obtained is

$$v = 2·9989 \times 10^{10}.$$

The authors think that in this determination, which they regard as simply a preliminary one, the mean error between the different measurements is 1 in 1000.

A PAPER upon the subject of vertical earth-air electric currents was presented to the Philosophical Society of Washington by Dr. L. A. Bauer on January 9. Vertical earth-air electric currents were first revealed by Dr. Adolf Schmidt, of Gotha. In his mathematical analysis of the earth's magnetic field—the most carefully executed analysis up to date—he reached the following conclusion: The earth's total magnetic force consists of three parts, viz. (1) the greatest part; this is to be referred to causes *within* the earth's crust, and possesses a potential. (2) The smallest part, about 1/40 of the entire force; this is due to causes *outside* of the earth's crust, and likewise possesses a potential. (3) A somewhat larger part than the preceding; this does not possess a potential, and, in consequence, points to the existence of vertical electric currents. These currents amount, on the average, for the earth's entire surface to one-sixth of an ampere per square kilometre. The existence of such currents is indicated by the non-vanishing of the line integral of the earth's horizontal magnetic force resolved along a closed curve of the earth's surface. Gauss carried out this test in a special case, and finding the integral practically zero, he assumed that the entire force is due to a potential. More recently Prof. Rücker applied the same test. He found "no evidence in favour of the existence of vertical currents" over a region of the earth—the British Isles—which had been very minutely surveyed. The results of some preliminary investigations being confirmatory of Schmidt's conclusion, Dr. Bauer determined to carry out the test in a thoroughly systematic manner, viz. to take as the closed curves parallels of latitude. The results obtained confirm those of Dr. Schmidt's more elaborate investigation. Summing-up, Dr. Bauer finds that:—"There are vertical electric currents which pass from the air into the earth, and back again into the air. Between 60° N. and 60° S. the average current intensity per square kilometre is about one-tenth of an ampere."

AT Governor's Island, a few days ago, Lieut. Hugh D. Wise, of the United States Army, made a very successful ascent by kites. He used four kites, a modification of the Hargrave invention, and weighing about 16 pounds each. The kites were attached to a windlass running out a ¼-inch manilla cord connected with an iron ring drawn up fifty feet above the ground. From the ring the kites ran up on two 1-inch cords. Two kites, one above the other, were attached to each of the latter cords. To the ring was also attached a tackle and block, running a heavy rope to the ground. On this rope Lieut. Wise was drawn up, and remained for a considerable time at a height of about 42 feet, surveying the environment on all sides with his field-glass. The wind was blowing fifteen miles an hour, and the pull of the kites was about 400 pounds.

A SHORT but interesting account of the earthquake of last December 17, founded partly on newspaper descriptions and partly on the notes of observers, is given in Symons's *Meteorological Magazine* for January. The first of the two maps, which illustrate the paper, shows many of the places where the shock was felt and where structural damage occurred. The writer remarks that the area affected was apparently 350 miles in diameter, and contained about 100,000 square miles; and that the part within which damage was produced, which is nearly central with regard to the former, is about 130 miles from north to south, and of a maximum breadth of 40 miles, thus containing nearly 4000 square miles, or about ten times the corresponding area of the Essex earthquake of 1884. He believes that there is evidence that the shock was one of a series which can be traced back for more than six centuries, and gives small sketch-maps showing the approximate boundaries of the shocks of the years 1248, 1574, 1705, 1863, 1868, and 1896. Taking the initial time of the recent disturbance as 5.32 a.m., and Hereford as the centre, the more careful time records appear to show that the velocity of the earth-wave may have been about 30 miles a minute. The paper concludes with a list of the minor shocks, a series of records of the luminous phenomena, which, it is suggested, prove only that a local thunderstorm occurred at about the same time as the shock, and some references to the sound which accompanied the earthquake.

DURING the last few years, one of the principal sources of income of cold-storage companies in the United States has been

derived from the storage of furs, rugs, and valuable woollen goods during the summer months to prevent damage by the larvæ of clothes moths, clothes beetles, and allied insects. This development raised the question as to the exact or approximate temperature at which furs and similar goods should be kept in order to maintain in a state of inactivity any destructive insects which they might contain. The matter was referred to Dr. L. O. Howard, entomologist to the U.S. Department of Agriculture, but he was unable to furnish the necessary information, or to find any facts bearing upon the subject. A series of experiments were, therefore, begun, and the results are described in the *Proceedings* of the Eighth Annual Meeting of the Association of Economic Entomologists, received a few days ago. The insects subjected to experiment were the common clothes moth, the black carpet beetle, the leather beetle, the dark meal-worm, and a cabinet beetle. The results seem to show definitely that it is perfectly safe to keep materials infested by any of the insects mentioned at a temperature of 40° to 42° F. during the summer months, and that the cold-storage companies, which have been keeping the goods at temperatures of 12° to 20°, have been wasting energy in producing a temperature about 20° lower than is required. A number of valuable papers on economic entomology will be found in the *Bulletin* (No. 6 of the U.S. Department of Agriculture) in which Mr. Howard's paper appears.

EMBRYOLOGICAL research is now flourishing in the University of Tōkyō, Japan. Part 1, vol. x. of the *Journal* of the College of Science in that University, consists of an elaborate memoir, by Prof. K. Mitsukuri, on the "Fate of the Blastopore, the Relations of the Primitive Streak, &c., in Chelonia." The text is in English, and there are eleven plates containing numerous figures, both of surface views of embryos and of sections. The memoir is appropriately dedicated to the memory of the late F. M. Balfour, of whom the author is one of the distinguished pupils. The embryos studied were those of three species of turtle common in Japan, those of two of them having been obtained in abundance with great facility at a turtle farm. The observations throw a great deal of light on the nature of the primitive streak, and on the formation of the posterior end of the embryo, and the general result is to confirm and elaborate in detail the interpretation of reptilian development in its early stages, which is explained in Balfour's "Comparative Embryology." New suggestions, however, are made concerning the relations between the mode of development and the evolution of yolk in the various classes of vertebrates.

THE development of the renal and generative organs in dog-fishes is one of the most important subjects in vertebrate morphology, and has occupied much of the attention of several eminent investigators. Prof. Carl Rabl has studied the matter in great detail during the past few years, and in the current number of the *Morphologisches Jahrbuch*, edited by Gegenbaur, gives a new description of the history of these organs in the embryo, and reconsiders various questions concerning their evolution.

THE horary values of the magnetic elements at Copenhagen, during the years 1893-94, are given in the "Annales de l'Observatoire magnétique de Copenhague," prepared by Dr. Adam Paulsen, Director of the Denmark Meteorological Institute, and just published.

MESSRS. LONGMANS, GREEN, AND CO. have published, as a pamphlet of twenty-four pages, the first part of "Exercises in Practical Physiology," dealing with elementary physiological chemistry. Prof. A. D. Waller, F.R.S., and Mr. W. Legge Symes are the authors: and the exercises they give should be of great assistance in laboratories of physiological chemistry.

A COURSE of six short lectures and demonstrations on fish and fisheries, free to the public, is now going on at University College, Liverpool. Prof. Herdman opened the course with an account of the present position of our fishing industries, and the advantages to be gained from biological investigations. Mr. R. A. Dawson followed with a lecture on the need and object of Sea Fishery Committees, and on the different methods of fishing in the Lancashire Sea Fisheries District. Some methods of fishing, and of fish culture in other European countries, were described by Mr. R. L. Ascroft on Monday evening. The three ensuing Monday evenings in this month will be devoted to fish parasites, and some constituents of the food of fishes, by Mr. Isaac C. Thompson; the habits and life-history of crabs and lobsters, by Mr. Andrew Scott; and the bacteriology of fish, and the connection of fish with disease, by Prof. Boyce. The Lancashire Sea Fisheries Committee is fortunate in being able to arrange a course of lectures so very serviceable to all who are interested in the fishing industry of the district.

SOMEWHAT remarkable results have been obtained by Messrs. T. Paul and B. Krönig in an investigation into the behaviour of bacteria towards chemical reagents, which appears in the December number of the *Zeitschrift für physikalische Chemie*. A definite number of organisms are exposed to the action of a solution of the disinfectant for a definite time; after complete removal of the disinfectant, the number of organisms still capable of development is determined. The spores of the anthrax bacillus were used in the greater part of the experiments. It is found that the different salts of a metal possessing a specific poisonous character—mercury, for example—are not by any means equally deadly. Under otherwise similar circumstances, those salts which are electrolytically dissociated to the greatest extent are most active. For example, a solution of mercuric chloride contains very many more mercury ions than one of mercuric cyanide of the same concentration, and the latter salt is very much less deadly than the former. The addition of sodium chloride to a solution of mercuric chloride diminishes its disinfecting power to a very marked extent; in this case, also, the number of mercury ions is diminished by the presence of the salt. This is of practical importance, because the addition of salt to mercuric chloride solutions is often recommended in order to increase its solubility. Similar results are obtained with silver salts; such salts as the nitrate, chlorate, and benzene sulphonate, which are dissociated into their ions to a considerable and approximately equal extent in aqueous solution, have nearly the same disinfecting action, while the addition of sodium thiosulphate or of potassium cyanide, with which the silver ions combine to form complex ions, practically destroys the disinfecting action altogether. The disinfecting power of solutions of bases or of acids depends, on the whole, on the strength of the base or acid—that is, on its degree of electrolytic dissociation. Although in all these cases the influence of the dissociation is plainly apparent, the specific action of the anion and of the undissociated molecule is by no means to be neglected. Hydrofluoric acid, for example, though a comparatively weak acid, has a more powerful action than acids like nitric or hydrochloric. Of practical interest is the fact that silver nitrate has a maximum disinfecting power when dissolved in 50 per cent. alcohol, while with mercuric chloride the maximum occurs at 25 per cent. Solutions of these salts in absolute alcohol are practically without effect on anthrax spores.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Miss E. Blanche Joyce; a White-backed Piping-Crow (*Gymnorhina leuconota*) from Australia, presented by Mr. H. Brame; a Kinkajou (*Cercoleptes caudivolvulus*) from South America, deposited; a Black Lemur (*Lemur macaco*, ♀) from Madagascar, purchased.

OUR ASTRONOMICAL COLUMN.

TABLES FOR FINDING LATITUDE VARIATIONS.—Prof. S. C. Chandler gives, in the *Astronomical Journal* (No. 392), tables for finding the variations of latitude for the present year, these being a continuation of those published in an earlier number of the same journal (No. 193). The formulæ used in the computation were derived entirely from observations made previous to 1894·0, so that, as is suggested, a good opportunity is given of comparing the theoretical with the observational places obtained since that date. Such a comparison made by him shows that only an average difference without regard to sign of $\pm 0''\cdot041$ is indicated, a quantity sensibly not greater than the uncertainty of the observed points themselves. This satisfactory conclusion shows us then that predictions of the movements of the pole may, with no reasonable doubt, be made for several years beforehand. From an investigation, which Prof. Chandler has in hand, he informs us that a discussion of the whole series of observations from 1889 to 1896·5, demonstrates that the radius of the 428-day revolution has been diminishing in accordance with the law given by him (Equation 52, *Astr. Journ.*, 322), but at a slightly greater rate. He further adds that a comparison of the observations at Kasan in 1895 and 1896, in conjunction with those made in Central Europe, confirms the fact of the "remarkable eccentricity of the annual ellipse which was developed from the previous European and American observations."

THE TRIFID NEBULA.—Prof. Pickering, in the Harvard College Observatory Circular (No. 15), gives a brief account of the performance of the Bruce photographic telescope which is now erected at Arequipa. This instrument was generously given by Miss Catherine Bruce, as it had been suggested that a telescope of 60 cm. aperture and 343·8 cm. focal length would give most probably excellent photographic results. Since it was set up, it has been in constant use by Prof. Bailey, and a plate accompanies the Circular to serve to illustrate the work already accomplished. The original negative was taken last year, on June 11, with an exposure of three hours, on a plate 14×17 in. The region covered extends in R.A. from 17h. 40m. to 18h. 10m., and in declination from $-20°8'$ to $-26°5'$. The two nebulæ on that part shown in the figure are the Trifid Nebula N.G.C. 6514 and N.G.C. 6523. It is stated that photogravures of two regions have been prepared, and a limited distribution, mainly to observatories, is being made of them. It is also proposed to issue maps of other portions of the sky, such as the Magellanic Clouds. It was originally intended to map the entire sky, but it is now thought better to furnish contact prints on glass from the original negatives to such astronomers as will make use of them.

Excellent results have already been obtained with objective prisms, and these, as we are informed, will be communicated in a future Circular.

THE PERIOD OF SIRIUS' COMPANION.—In this column for November 19, we gave the measures made by Prof. Aitken of the companion of Sirius, and pointed out that the position angle differed from that reported by Dr. See. In the current number of the *Astr. Nach.* (No. 3400), Herr H. J. Zwiers communicates a short note, in which he has taken the mean of the new measures made at the Lick Observatory—namely :

1896·8235 ... Position angle 189·28° ... Probable error $\pm 0·67°$
Distance ... 3·74″ ... ,, ,, $\pm 0·12″$

and compares this place with that given by the computation of the orbit (*Astr. Nach.*, 3336), which is

Poslion angle 185·99°
Distance ... 4·05″

The difference, observation minus calculation, gives for the two measures : position angle + 3·29° and distance − 0·31″, showing that the computed place is sufficiently near until more observations have been obtained. Prof. Auwer's suggestion that the period may be a little longer than 49·4 years is thus endorsed, while Herr Zwiers' period of 51·10 years gives a somewhat too slow a movement.

HEAT RAYS OF GREAT WAVE-LENGTH.—It is well known that the spectrum we see when observing an ordinary red-hot poker through a prism is only a fractional part of a much more extensive one. In addition to the common light waves there are several other kinds, such as electrical, heat, &c., all of which may form part of the spectrum in its entirety, and the attempt has often been made to increase our knowledge over the broad region between the electrical and light waves. This may be done by either reducing the wave-lengths of electrical oscillations, or by the discovery and measurement of longer heat waves. In the pamphlet we have before us, a reprint from the *Physical Review* (vol. iv. No. 22), Messrs. H. Rubens and E. F. Nichols have just completed a very interesting investigation of the infra-red waves of great wave-length. The new theories of dispersion have suggested a method by means of which homogeneous rays of great wave-length may be obtained, and in sufficient quantity to make the determination of their properties and wave-length possible: this can be done, further, without the intervention of either a prism or grating. The authors make "reflection" the basis of their investigation, and in the instrument they devised they have chosen three reflectors of the same substance as the light source used. The bolometer employed was one of platinum, after the design of Lummer and Kurlbaum, the absorbing layer being a coating of platinum black, deposited electrically.

The two substances studied were quartz and fluorite. In the case of the former, the mean wave-length of the observed rays gave in the first and third orders 0·00887 mm. and 0·00882 mm. respectively. The agreement between the two values lies well within the limit of probable error. For fluorite the maximum energy in the diffraction spectrum of the first order corresponded to a wave-length of 0·0244 mm., the mean from other series varying from 0·024 mm. to 0·025 mm.

The authors remark that if these values be compared with those computed from the Kettler-Helmholtz dispersion formula for the middle of the absorption bands, in each case the observed value for quartz is 10 per cent., and for fluorite 20 per cent. less than the computed. As inaccuracies may arise from the computed values, and there may be errors in the experimental values, such as, for instance, a variation in the absorption of platinum black with the wave-length, yet "one is justified in regarding the agreement between the observed and computed wave-lengths as close enough to confirm the utility of the theories involved."

The rays corresponding to the infra-red absorption band in fluorite lie thus almost exactly midway between the shortest ultra-violet rays of Schumann ($\lambda = 0·0001$ mm.) and the 6 mm. electrical waves of Lebeden, reckoning the interval according to octaves, as is customary in acoustics.

The authors hope, moreover, to be able to refine the present method of observation, and study waves of greater wave-length ; and, by means of an improved radiometer, obtain a much higher degree of sensitiveness.

THE VALUE OF PATHOLOGICAL RESEARCH.[1]

ON the occasion of the jubilee of Queen's College, Belfast, last month, the new physiological and pathological laboratories were formally opened by the Lord Lieutenant. On the following day an address of welcome and congratulation was presented by the North of Ireland Branch of the British Medical Association and the Ulster Medical Society to Lord Lister, who, after receiving it, spoke as follows :—

It gave me very great pleasure to witness the opening of the physiological and pathological laboratories yesterday by His Excellency the Lord Lieutenant. Such an establishment is calculated to be of enormous advantage to the North of Ireland. The benefits which it will confer will be of various kinds. In the first place it will be of very great assistance to the medical practitioner in forming his diagnosis of the disease of the patient he has to treat. In these days the knowledge of pathology has made immense advances ; and, at the same time, along with those advances in pathological knowledge, there has arisen increased complexity in the methods of examining pathological objects. Section cutting, staining, microscopic examination—these are matters of the utmost moment ; and yet for the general practitioner there may be neither the apparatus nor the time requisite for that kind of investigation. It will, therefore, be of great advantage to the practitioner, when he has removed or in any way obtained a portion of a morbid growth, to send it to a central institution, and have absolutely definite informa-

[1] An address delivered January 20, in connection with the opening of the new physiological and pathological laboratories in Queen's College, Belfast, during the celebration of the jubilee of the College, by Lord Lister, P.R.S.

tion as to the precise nature of the disease with which he has to deal. Then, as regards the bacteriological department—there, again, diagnosis will be greatly facilitated. You are most of you aware that the diagnosis of diphtheria can now be made by bacteriological examination. It is of the utmost importance in the treatment of a case of diphtheria that its nature should be distinctly defined; that it should be known with certainty whether it is true diphtheria or a disease which closely simulates it, and may deceive the most experienced practitioner, and yet have none of the deadly characteristics of true diphtheria. Now for the future any medical man in the North of Ireland will only have to send, in a suitable tube, which will be provided by the institution, a little of the false membrane in the case with which he is dealing, and in a very short time he will have sent to him a bacteriologically made diagnosis of whether it is a case of true diphtheria or not. Again, with reference to what is more immediately connected with the objects of this College, such an institute will be of very great help in the training of students in their education for the medical profession. In it the student will have the opportunity of practically studying the various forms of morbid growths and the diseases which are of the nature of microbes. These are days when the subjects of medical examination are becoming more and more complex, and the student is too much tempted to get up his knowledge in a superficial way, cramming to satisfy the examiner, rather than to obtain thorough-going practical information. That is more especially the case when the student is not examined by his own teachers, under whom he might work with some confidence that his labour would not be thrown away with reference to that really subordinate, but in his eyes vastly important, matter of the passing of his examination. May I venture to interpose a remark on that point, and to express the hope that the time is not very far distant when the great northern metropolis of Ireland will have its own university, a true teaching and graduating university on the same lines as most of the German universities and the Scotch? But passing from that, independently altogether of the difficulty a student may have in preparing for examination by strangers, the great complexity of the subjects of medical education makes it extremely important that there should be afforded ample opportunities of practical study. The bacteriological department will be of peculiar value in the education of the student. It will in the first place convince him of the reality of the microscopic foes with which we have at the present day so largely to deal—the microbes, which are the cause of so large a proportion of human disease. He will not only read that such things are, and when he gets into practice perhaps forget that they exist, but he will know them as acquaintances. He will see the evidence not only of their existence, but also of their effects. The bacteriological training will besides be of special advantage in teaching the student accurate observation and also dexterity of manipulation—both most important matters in a medical man's practice. If a student is told to prepare a culture of a particular microbe in a state of purity, in order to do that he must be very sharp indeed in his observations, and very clever, too, in his manipulations; and if he fails, the fact will very soon declare itself. There will be an impure culture, and instead of having only the one microbe he wished to cultivate, with its well-known special characteristics, it will be seen that he has allowed others to get in at the same time. His own imperfections will thus declare themselves; but he will persevere, and go on and on until he becomes perfectly competent to produce a pure culture. This will be of great importance in his education. There is another aspect of a pathological institute which I feel some delicacy in alluding to, because there are some people who take strange views with regard to these matters—exaggerated views. There are people who do not object to eating a mutton-chop—people who do not even object to shooting a pheasant with the considerable chance that it may be only wounded and may have to die after lingering in pain, unable to obtain its proper nutriment—and yet who consider it something monstrous to introduce under the skin of a guinea-pig a little inoculation of some microbe to ascertain its action. Those seem to me to be most inconsistent views. With regard to all matters in which we are concerned in this world, everything depends upon the motive. A murderer may cut a man's throat to kill him; any one of you medical students may have to cut a man's throat to save his life. The father who chastises his son for the sake of the good of his morals is a most humane man: a father who should beat his son for the mere sake of inflicting pain upon him would be an inhuman monster. And so it is with the necessary experiments upon lower animals. If they were made, as some people seem to assume, for the mere sport of the thing, they would be indeed to be deprecated and decried; but if they are made with the wholly noble object of not only increasing human knowledge, but also diminishing human suffering, then I hold that such investigations are deserving of all praise. Those little know who lightly speak on these matters how much self-denial is required in the prosecution of such researches when they are conducted, as indeed they always are, so far as I am aware, with the object of establishing new truth. The exercise of a little charity might lead those who speak of us as inhuman to reflect that possibly we may be as humane as themselves. The profession to which I have the great honour to belong is, I firmly believe, on the average, the most humane of all professions. The medical student may be sometimes a rough diamond; but when he comes to have personal charge of patients, and to have the life and health of a fellow-creature depending upon his individual care, he becomes a changed man, and from that day forth his life becomes a constant exercise of beneficence. With that beneficence there is associated benevolence: and, in that practical way, our profession becomes the most benevolent of all. If our detractors knew this, common sense would enable them to see that our profession would not be unanimously in favour of these researches if they were the iniquitous things which they are sometimes represented to be. I was reading the other day a very interesting account of Pasteur's work on rabies, written by one who was associated with him from an early period (M. Duclaux). It had been established that the introduction of a portion of the brain of a mad dog under the skin of a healthy animal was liable to cause rabies, and Pasteur had reason to believe that it was principally in the nervous centres that the poison accumulated. He felt a very strong desire to introduce some of the poison into the brain of an animal; but he was a peculiarly humane man. He never could shoot an animal for sport. He was more humane than the great majority of human beings; and for a long time he could not bring himself to make the experiment of trephining an animal's skull, and introducing some of the poison of rabies into the brain. He was exceedingly desirous of doing it to establish the pathology of the disease, but he shrank from it. On one occasion, when he was absent from home, one of his assistants did the experiment, and when Pasteur came back he told him that he had done so. "Oh!" said Pasteur, "the poor creature! His brain has been touched. I am afraid he will be affected with paralysis." The assistant went into a neighbouring room and brought in the animal, which was a dog. It came in frisking about and investigating everything in a perfectly natural manner; and Pasteur was exceedingly pleased, and though he did not like dogs, yet he lavished his affection upon that particular animal and petted it; and from that time forth he felt his scruples need no longer exist. The truth is that the pain inflicted by this process of trephining is exceedingly slight, and yet the operation is sometimes described as being a hideously painful one. That is a mistake. In point of fact the operation is always done now under anæsthetics, so that the animal does not feel it at all; but even without that the operation is not seriously painful. I look forward to the time when there will be an institute in connection with this College, where investigations of the kind to which I have referred can be carried on, and where pathological knowledge of the first importance may be promoted. Think also of the practical advantages of an institution where the materials can be provided for the treatment of diseases on the principles which have been recently established. It appears to be now placed beyond doubt that that dreadful disease diphtheria may by the antitoxic treatment be reduced in mortality from about 30 per cent. to about 5 per cent. if the proper material is promptly used. It is exceedingly important that in a city like Belfast the supply of such material should be within easy reach of the practitioner—that he should not be compelled to send to London for the requisite serum, and thus lose much valuable time. Every hour that is lost in the treatment of a case of this nature is a very serious loss indeed. But it is by no means only in diphtheria that such an institute is likely to confer benefits of this kind. In the case of the streptococcus, which is the cause of erysipelas and kindred disorders, including that very terrible disease, puerperal fever, there are very promising indications that the use of antitoxic serum will

rescue patients from otherwise hopeless conditions. Let any one picture to himself the case of a young wife after her first confinement afflicted with this dreadful puerperal fever, and doomed under ordinary treatment to certain death. The practitioner makes an injection of this serum under the skin, with the result that the lady rapidly recovers, and in a few days is perfectly well. Let any man conceive such a case as this, and all objections to the investigations necessary to bring about such a state of things must vanish into thin air. So soon as our poor selves are directly concerned our objections disappear. If a tiger threatened to attack a camp, who would care much about what kind of a trap was set for it, or what suffering the trap caused the animal, so long as it was caught? When the matter affects only the welfare of others, including generations yet unborn, the good done does not appeal to the individual, and the objector sees only the horrors of modern scientific investigation; of which horrors, however, he quickly loses the sense as soon as he becomes personally concerned.

On the occasion of the funeral of that illustrious investigator to whom I have before referred, I visited the Institut Pasteur, and there was shown preparations of the microbe of the plague discovered at Hong Kong in 1894 by M. Yersin. And I was told by M. Roux, that Yersin, whom he knew intimately as formerly his colleague, had lately been treating in China several cases of that fearful disease with serum prepared at the Institut Pasteur on the same lines as that used for diphtheria. Cultures of the plague bacillus had been taken to Paris, and at the Institut, under the most rigorous precautions, the serum had been prepared. At the Institut they did not think they had succeeded in producing a very powerful serum, judging from its action on animals; but in the human subject it seems to have proved most potent. M. Yersin obtained serum sufficient for the treatment of twenty-six cases of the plague. The mortality from the disease at the time was above 80 per cent. The first case which he treated was that of a young man, in whom a "bubo," characteristic of the disease, was present, and the patient, already delirious, was completely despaired of. A little of the serum was introduced, and, to M. Yersin's absolute amazement, on the following day the young man was well, the bubo having almost entirely disappeared. And, moreover, of the twenty-six cases in which M. Yersin used the serum, twenty-four recovered; while in the remaining two Yersin felt that he was called in so late that their cases were hopeless. I would not have referred to these facts did I not know that the person from whom they were obtained was absolutely trustworthy. We cannot tell how soon the plague may visit these shores. We know that in one of our great dependencies—Bombay—it is already prevalent in a very severe form, and has already cost many lives. We know that a ship may carry the disease; that rats are liable to contract it, and that a rat making its escape from a ship coming from Bombay, say, to the Thames or to Belfast Lough, may carry the plague ashore, and that the taint may be communicated to human beings, with dreadful results. I would not say that there are not slums in the city of Belfast which might harbour the plague. So you can easily recognise how vastly important it would be to have means at hand whereby, in the simple way I have described, the disease may be combated. I have, I think, said enough to show the vast importance of an institute of such a character, and I look forward to the time when you will have such an establishment thoroughly equipped for its beneficent work.

There is another department in connection with medical education in this city about which I cannot speak in the same terms of praise as I can with reference to the new laboratories, and that is the hospital. No doubt the Royal Hospital, which I had the honour of visiting for the first time yesterday, is a fine institution; but it is altogether inadequate to the requirements of this great and rapidly-growing city. It is inadequate, whether for affording means of clinical instruction to students or for dealing with the diseases of your large and increasing population. But I am glad to know that there is a prospect of better things before long. I understand that it has been not merely contemplated, but determined, to build a large new hospital provided the requisite funds can be obtained; and I have been informed that within six weeks of the initiation of the movement more than half the necessary sum has been raised. I have no doubt that the munificence of the merchant princes of Belfast will soon provide the balance. Therefore, whichever way I look at this jubilee, I feel that the College, more particularly with regard to its medical school, is entering upon a new era of prosperity. I rejoice with you in the fact, and I have felt it a great privilege to take part in your celebration.

[Since this address was delivered, the last number of the *Annales de l'Institut Pasteur* has appeared, containing a paper by M. Yersin, describing his experience above referred to. The details which he gives of the cases confirm in a remarkable manner the conclusion which the mere numbers suggest. Just as in diphtheria, and exactly as must occur if the antidote is really efficacious, the cure was most rapid when the treatment could be commenced on the first day of the disease; speedy also, but less so, when it was begun on the second day; and so from day to day till the fifth. Four patients were treated at this very late period, and the only failures were in two of these. More of the serum also was required in the more advanced cases.

Equally striking was the manner of recovery. In none of the twelve cases in which treatment commenced within two days of the onset of the complaint did the bubo suppurate. And in those of a later period in which matter did form, the abscess closed rapidly after being opened, instead of healing tediously, as it does when recovery takes place without this treatment. And the patients, instead of having a lingering convalescence, were healthy men and women in a time which was always relatively short, and astonishingly so when the treatment had been commenced early. These details are so extraordinarily confirmatory that, small though the number of cases is, they carry conviction to my own mind.

It gives me the most profound satisfaction to be able to state on the authority of the India Office, that the Bombay Government intend to employ M. Yersin, now on his way to the stricken region, to give a full trial to his method, and I have also learned through another channel that within a fortnight from this time (February 1) the serum treatment will probably have begun in Bombay. LISTER.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The election to the Professorship of Geology will take place during the present term.

This term the usual courses of lectures are being given in the various departments of Natural Science. Prof. H. H. Turner is lecturing on Elementary Astronomy, Prof. Odling on Organic Chemistry, and Profs. Vines and Gotch are continuing their advanced courses in Botany and Physiology respectively.

Prof. H. A. Miers is giving a series of lectures on the Relation between Chemical Composition and Crystalline Form.

In the Department of Comparative Anatomy, Prof. Ray Lankester is lecturing on Reptiles and Birds, Mr. R. W. T. Günther on Brachiopoda and Polyzoa, Mr. Barclay Thompson on the Osteology of the Sauropsida and on Sauropsidan Palæontology, and Mr. G. C. Bourne is conducting a class for the study of Vertebrate Histology. In the Hope Department, Prof. Poulton will give a series of lectures on the Age of the Earth.

Prof. Tylor is lecturing on the Early Stages of Knowledge, and Mr. Balfour on Realistic and Decorative Art of Primitive Peoples.

Elementary courses in the different departments are being given by Profs. Gotch and Vines, Dr. Benham, and Messrs. Churchill, Baynes, Watts, and Vernon Harcourt.

CAMBRIDGE.—The Gilbey Lecturer in the History and Economics of Agriculture will give four lectures this term on Fridays, at two o'clock, beginning on February 12. His subject is Ancient and Mediæval Agriculture.

At the matriculation on January 28, eighteen additional Freshmen were entered, bringing the total for the academic year up to 923.

Mr. W. Gardiner, F.R.S., has resigned his University Lectureship in Botany on his appointment as Bursar at Clare College, of which he is a Fellow.

DR. T. E. THORPE, F.R.S., will distribute the certificates in science subjects to evening students at the East London Technical College, People's Palace, on Monday, February 8.

MR. GARRETT A. HOBART, Vice-President-elect of the United States, has given to his *alma mater*, Rutger's College, 5000 dols. for the general expenses of the college.

AT the Queen's Hall, Langham Place, to-morrow, February 5, the Prince of Wales will present the certificates to the winners of scholarships and exhibitions of the London County Council Technical Education Board.

THE Technical Instruction Committee of the Northumberland County Council have intimated that they would not be indisposed to make a grant to the Northumberland Sea Fisheries Committee, provided the latter will undertake to arrange for something definite in the direction of hatchery, or arrange some clearly-defined work of an educational value. The Sea Fisheries Committee are making inquiries with the object of devising and establishing experimental work in hatchery.

THE Durham County Council last week sanctioned the expenditure of no less a sum than £2254 for the erection of a "band-room" by the committee of the Earl's House Industrial School, which is under its control. Though it was rightly objected by one councillor that instrumental music was not legitimately a part of an industrial training, yet, following the lead of a member of Parliament present, the Council approved of the grant on the ground that band-playing "tends to elevate the boys, and make them better citizens."

IT is proposed that Staffordshire shall unite with Shropshire and Warwickshire in a scheme which shall provide advanced and elementary technical education, in colleges and schools specially adapted for the work, for the sons and daughters of farmers. The Staffordshire Committee are also to appoint a lecturer on pottery and porcelain, with the object of improving the ceramic industry of the northern part of the county, as well as appoint a lecturer and establish a metallurgical laboratory at Wednesbury in South Staffordshire.

PROBABLY the scholarships established by Sir Joseph Whitworth have been the means of bringing more talented young men to the front rank of engineers than any similar foundations. By a will just made known, it appears that the late Lady Whitworth recognised the advantages which scholarships offer to earnest students. She bequeathed such a sum as will provide a permanent income of £100 a year to be applied as "Lady Whitworth Scholarships" in connection with the public elementary school or schools established in Darley Dale, for the purpose of enabling scholars therein to maintain themselves at such schools wholly or partially, or to proceed to other place or places of higher education. The selection of scholars has always to be made according to merit, and not on the mere ground of poverty, or any considerations of private personal favour.

THE great Fayerweather Will contest has just been finally settled by the Court of Appeals of the State of New York, confirming the judgment of the Supreme Court, and dividing the residue of the estate, amounting to about 3,000,000 dols., equally among the following educational institutions, in addition to the following named bequests, which have already been divided among them under the ninth paragraph of the will:—Yale University, 300,000 dols.; Columbia and Cornell University, 200,000 dols. each; Bowdoin, Dartmouth, Williams, Amherst, Hamilton and Maryville College, Wesleyan, Lincoln and Hampton University, and the University of Virginia and of Rochester, 100,000 dols. each; Union Theological Seminary, Lafayette, Marietta, Adelbert, Wabash and Park College, 50,000 dols. each.

WE have received a copy of the scheme agreed to between the Leathersellers' Company and the Executive Committee of the City and Guilds of London Institute for the administration of a grant of £150 a year, offered by the Leathersellers' Company, to be applied to chemical research. It has been resolved that the fellowships shall be open to natural-born British subjects, who are (*a*) students of the Institute who have completed a full three years' course of instruction in the chemical department of the Central Technical College, or (*b*) candidates duly qualified in the methods of chemical research in its relation to manufactures, without restriction as to age or place of previous study, but preferably to class (*a*). Every fellowship will be tenable for part of a year or for one year, and may be renewed for a second or third year, but in no case can be held for a further period. Holders of fellowships must devote their whole time to the prosecution of research. The researches have to be carried out at the Central Technical College. Applications for fellowships must be made in writing to the Hon. Secretary of the Institute, at the Head Office, Gresham College, E.C., and must state the name of the proposed research and the qualifications of the candidate.

THE report of the Director of Technical Instruction to the County Council for the County Palatine of Lancaster for the year ending August 31, 1896, which is to be presented to the meeting of the Council on February 4, is of the most exhaustive nature. The amount which the Technical Instruction Committee resolved to distribute among the urban and rural districts of the county for the year was £24,225, being a decrease of £4285 on the sum distributed in the previous twelve months. Short accounts of the various conferences at which the Lancashire County Council have been represented throughout the year are given, and also full information respecting the scholarships awarded by the Council, and of all grants made in aid of the different branches of study throughout the county. Under the heading "Renewal of Scholarships," we notice that a Lancashire student at Cambridge, who was Second Wrangler in 1895, has been granted a special scholarship of £60 a year to enable him to complete the terms required for a Fellowship of his college, and to make it possible for him to compete for the Smith's Prizes. A series of useful tables showing the whole of the scholarships and exhibitions awarded, as well as the total number of students receiving instruction, makes it possible to compare the work of the session 1895 6 with that of previous years. It is interesting to note that the amount actually awarded for these purposes during the year under consideration more nearly approximated to that set aside for the purpose than in any previous session. The highest number of entries of students in all subjects was in the year 1893-4, when the total reached 58,534; with the exception of this particular year there has been a steady increase up to 1896, when the total was 54,719. The excellent report of the work of the County Council Farm at Hutton completes the history of a most satisfactory year's work.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 17, 1896.—"On the Effect of Pressure in the Surrounding Gas on the Temperature of the Crater of an Electric Arc. Correction of Results in former paper." By W. E. Wilson, F.R.S., and G. F. Fitzgerald, F.R.S. Received November 30, 1896.

This paper describes experiments made with the surrounding gas as air, oxygen, hydrogen, and carbon dioxide. It was found that with air and oxygen large quantities of NO_2 are formed at high pressures, and that observations of the radiation at these pressures is consequently impossible. The experiments described in the former paper were made with nitrogen, and there is every reason to believe that the remarkable diminution in radiation then observed was due to the nitrogen containing sufficient oxygen as an impurity to produce NO_2. Experiments with hydrogen showed that in this gas the arc is long and thin with a red line down its centre, giving the hydrogen lines not nearly so expanded as in a spark spectrum at the same pressure. Observation of the crater under high pressures of hydrogen was impossible, because (*a*) only a very short arc could be maintained, and (*b*) soot trees and a deposit of graphitic carbon all round the margin of the crater at high pressures completely hid it. The experiments in CO_2 were the most satisfactory, but, owing to a variety of difficulties, it was found impossible to decide with certainty whether the crater was hotter or colder at high pressures.

A thermodynamic investigation of the rise of temperature in the crater due to increased pressure, on the assumption that the vapour pressure then is the same as that of the surrounding atmosphere, and that the latent heat of carbon is 4000 calories, leads to the conclusion that the temperature of the crater should have risen 220° C. for each atmosphere added, and that the radiation would have doubled for an increase of four atmospheres. Such a large increase would have, almost certainly, been observable in our experiments. Another difficulty, in the way of supposing that the carbon vapour near the crater is at the pressure of the surrounding atmosphere, is pointed out, arising from the slow evaporation of the carbon. Mercury evaporates very rapidly when used as the positive pole of an arc, and there seems no sufficient reason why the much less dense carbon vapour, at a much higher temperature, should evaporate so very much more slowly.

January 21.—"On *Cheirostrobus*, a New Type of Fossil Cone from the Calciferous Sandstones." By D. H. Scott, F.R.S., Hon. Keeper of the Jodrell Laboratory, Royal Gardens, Kew.

The cone described was found at Pettycur, near Burntisland, Scotland, in 1883, by Mr. James Bennie, of Edinburgh. The horizon of the deposit in which it occurs is that of the Calciferous Sandstones, at the base of the Carboniferous Formation. The specimen is calcified, and its structure preserved with remarkable perfection, allowing of the investigation even of minute histological characters.

The author is indebted to Mr. R. Kidston for the loan of his original sections of the cone, and for the opportunity of having additional sections prepared from the same block. No other specimen of the actual fructification is at present known, but a fragment of stem, of which sections are preserved in the Williamson Collection (now at the British Museum) appears to be the peduncle of a specifically identical cone.

It is necessary to establish a new genus for the reception of this fossil; the generic name proposed is *Cheirostrobus*, intended to suggest the *palmate* division of the sporophyll lobes (χειρ, hand). The species may be appropriately named *Pettycurensis*, from the locality where the important deposit occurs, which has yielded this strobilus, and so many other valuable specimens of palæozoic vegetation. The diagnosis may provisionally run as follows:—

Cheirostrobus, gen. nov.

Cone consisting of a cylindrical axis, bearing numerous compound sporophylls, arranged in crowded many-membered verticils.

Sporophylls of successive verticils superposed.

Each sporophyll divided, nearly to its base, into an inferior and a superior lobe; lobes palmately subdivided into long segments, of which some (probably the inferior) are sterile, and others (probably the superior) fertile, each segment consisting of an elongated stalk bearing a terminal lamina.

Laminæ of sterile segments foliaceous; those of fertile segments (or sporangiophores) peltate.

Sporangia large, attached by their ends remote from the axis, to the peltate laminæ of the sporangiophores.

Sporangia on each sporangiophore, usually four.

Spores very numerous in each sporangium.

Wood of axis polyarch.

C. Pettycurensis, sp. nov.

Cone, 3—4 cm. in diameter, seated on a distinct peduncle. Sporophylls, twelve in each verticil.

Each sporophyll usually sexpartite, three segments belonging to the inferior, and three to the superior, lobe.

Sporangia densely crowded.

Spores about 0·065 mm. in diameter.

The new cone, though widely different from any forms of Vascular Cryptogams hitherto recorded, appears to have more in common with *Sphenophyllum*—until now a perfectly isolated group of palæozoic plants—than with any other known genus.

The sum of its characters justifies the suggestion that *Cheirostrobus* may be provisionally placed in the same *phylum*, or main division of Pteridophyta, with *Sphenophyllum*, though indications of possible affinities in other directions are not wanting, and will be discussed on another occasion.

Cheirostrobus, even more than *Sphenophyllum* itself, appears to combine Calamarian with Lycopodiaceous characters, and might reasonably be regarded as a highly specialised representative of an ancient group of plants lying at the common base of these two series.

Mathematical Society, January 14.—Prof. Elliott, F.R.S., President, in the chair.—Prof. Sylvester, F.R.S., spoke on the partition of an even number into two primes, and answered numerous questions.—Mr. J. J. Walker, F.R.S., gave a solution of a certain quadratic vector equation.—The titles of the following papers were read: "Supplementary Note on Matrices," Mr. J. Brill; "Some Properties of Bessel's Functions," Dr. Hobson, F.R.S.—Mr. T. I. Dewar exhibited, with the aid of stereoscopes, several diagrams of the algebraic catenary.

Zoological Society, January 19.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—The Secretary exhibited a set of seven slightly enlarged photographs, illustrating the manner in which the rough-keeled snake (*Dasypeltis scabra*) swallows an egg. These had been taken from a living specimen in the Society's Gardens by Mr. R. F. Nesbit, by whom they had been presented to the Society. The specimen from which the photographs had been taken, measuring about 28 inches in length, was also exhibited.—The Secretary also exhibited a specimen of the Cerastes viper (*Cerastes cornutus*), which had been received in exchange from the Zoological Gardens, Ghizeh, Egypt, and had lately died in the Gardens. This was the specimen, with false horns made of hedgehog spines, which had been alluded to in the newspapers of the last few weeks. On examination it was found that one of the spines had been driven through the skull into the mouth of the snake, and this had probably caused its death.—Mr. Sclater exhibited a photograph of a young anteater (*Myrmecophaga jubata*) two days old, born in the Zoological Garden of Herr Adolf Nill at Stuttgart. Mr. Sclater remarked that this was the first instance, so far as he knew, of this animal having bred in captivity.—Lord Walsingham, F.R.S., read a paper entitled "A Revision of the West Indian Microlepidoptera, with Descriptions of New Species." This memoir gave a complete catalogue of all the species of Microlepidoptera known to occur in the West Indian Islands.—Mr. F. E. Beddard, F.R.S., read some notes on the anatomy of the manatee (*Manatus inunguis*) lately living in the Society's Gardens.—Dr. Lindsay Johnson read a paper on the ophthalmoscopic appearances of the fundus oculi in the Primates. Dr. Johnson had for some considerable time past devoted himself to the careful examination of the eyes of animals, using the means commonly employed by oculists when examining the human eye. He had found that the back of the eye when viewed with the ophthalmoscope presented different appearances in various animals. He showed that the eye of the negro only differed from that of the European in colour, that the higher apes closely resembled man in having binocular vision, and alone had the so-called *macula lutea*, or yellow spot, which is the seat of acute vision. In the lemurs and galagos the back of the eye differed entirely from that of the true monkeys, showing no *macula*. The galagos, which are night animals, had instead of a red or brown fundus a brilliant golden-yellow background to the eye.—Mr. Lydekker described certain deer of the *Cervus sica* group, living in the Duke of Bedford's Menagerie at Woburn.—A communication was read from Mr. Guy A. K. Marshall, on the butterflies of the genus *Teracolus*. The geographical distribution of the genus was described, and seventy-two species were enumerated, two of which were described as new.

Entomological Society, January 20.—Sixty-fourth Annual Meeting.—Prof. R. Meldola, F.R.S., President, in the chair.—An abstract of the Treasurer's accounts, showing a balance in the Society's favour, having been read by one of the Auditors, the Secretary, Mr. H. Goss, read the Report of the Council. It was then announced that the following gentlemen had been elected as Officers and Council for 1897:—President, Mr. Roland Trimen, F.R.S.; Treasurer, Mr. Robert McLachlan, F.R.S.; Secretaries, Mr. Walter F. H. Blandford and Mr. Frederic Merrifield; Librarian, Mr. George C. Champion; and as other members of the Council, the Rev. Canon Fowler, Mr. Herbert Goss, Sir George F. Hampson, Bart., Herr Martin Jacoby, Prof. Meldola, F.R.S., Mr. Osbert Salvin, F.R.S., Mr. James W. Tutt, and Mr. G. H. Verrall. The President then delivered an address, and took for the subject, "The Utility of Specific Characters from the Point of View of the Darwinian Theory." His remarks had reference to the paper on this subject, read last June before the Linnean Society, by Dr. A. R. Wallace, and the subsequent discussion. Prof. Meldola pointed out that the question of "utility," as necessitated by the theory of natural selection, had hitherto been made to depend too exclusively upon external and visibly manifest utility, a restriction which he did not believe to be warranted by facts. He argued in favour of a connection of the nature of correlation between apparently trivial external characters and latent physiological characters of great importance to the welfare of the species. From this point of view it was contended that the diagnostic characters used for purposes of description did not truly represent the sum total of the characters which must be regarded as specific. The President concluded by referring to the losses by death during the year of several Fellows of the Society and other entomologists, special mention being made of Mr. A. S. Olliff, Mr. Edward Armitage, R.A., Mr. Peter Inchbald, Miss G. E. Ormerod, M. Auguste Sallé, Mr. Arthur Dowsett, Herr Julius Flohr, Mr. J. Chappell, and Dr. Morawitz.—A vote of thanks to the President was proposed by Lord Walsingham, F.R.S., seconded by Mr. Osbert Salvin, F.R.S., and carried. A vote of thanks to the officers was then

proposed by Prof. Poulton, F.R.S., seconded by Mr. R. Trimen, F.R.S., and carried. Prof. Meldola, Mr. McLachlan, and Mr. Goss replied, and the proceedings terminated.

Royal Meteorological Society, January 20.—Annual General Meeting.—Mr. E. Mawley, President, in the chair.—The Secretary read the Report of the Council, which showed that the Society had made steady progress during the past year, there being an increase of seventeen in the number of Fellows.—The President then delivered an address on shade temperatures, in which he stated that of all meteorological observations there were none approaching in importance those made of the temperature of the air, generally known as "shade temperature." Indeed, the first question invariably asked in regard to almost any climate was as to its temperature. Mr. Mawley traced the history of the different methods of exposing thermometers since the time that regular observations of the weather had been made in this country. For many years open screens were most favoured by meteorologists, that devised by Mr. J. Glaisher, F.R.S., and the late Astronomer Royal (Sir G. B. Airy) being the pattern principally used. In 1864 Mr. T. Stevenson invented an admirable form of closed screen with louvred sides, which was considered preferable to the open type of screen, and has now almost entirely superseded the Glaisher stand. In 1883 the Stevenson screen was considerably improved by a Committee of the Royal Meteorological Society. Mr. Mawley then described his own experiments at Croydon and Berkhamsted as regards this improved screen, known as the Royal Meteorological Society's pattern. He showed that the only two defects which had been attributed to this form of thermometer exposure were virtually non-existent, and therefore advised its general adoption both in this country and on the continent. Mr. Mawley had recently made observations in the Stevenson screen, and also in the screens used in France and Germany, and the conclusion he had come to was that the results obtained in the Stevenson screen were not only the nearest to the true air temperatures, but also more likely to be strictly comparable with temperatures taken in a similar screen, but with different surroundings elsewhere.

Linnean Society, January 21.—Mr. C. B. Clarke, Vice-President, in the chair.—Dr. John Lowe exhibited some fossil antlers of *Cervus elaphus* of unusually large size from Southern Fen, Cambridge. With these were also exhibited various fragments of implements and weapons which had been discovered in proximity, showing that the animal had lived contemporaneously with man.—Dr. H. O. Forbes referred to similar antlers of great size which had been discovered in Lancashire during the cutting of the Manchester Ship Canal, and which were preserved in the Liverpool Museum.—Mr. J. E. Harting showed drawings of large antlers found at Bourne End in 1894, during the construction of the new viaduct over the Thames, and at Boston, Lincolnshire, in 1895, by a man ploughing. It was remarkable that while the antlers of Red Deer at the present day showed a marked deterioration in size and weight when compared with those obtained in a fossil state in England, this was not the case with the Roe Deer. He had seen no fossil horns of the Roe which were superior in size to those of the same species procurable at the present time in Scotland. The reason for this had not been explained.—Mr. Horace Monckton exhibited specimens of a common freshwater mollusc, *Limnæa peregra*, collected by him at the Howietoun Ponds, Selkirkshire, showing a variation from the normal type in being more or less banded. Mr. B. B. Woodward exhibited a similar variation in shells of *Limnæa stagnalis*, wherein the banding was longitudinal—a peculiarity which had been recorded by Mr. T. D. Cockerell.—Sir James Maitland, Bart., gave the results of an analysis which had been made of the water at Howietoun and Craigend, with a view to determine the bearing it might have on the growth of fish and variation in the shells of the mollusca referred to.—The Secretary read a letter from Mr. J. Y. Johnson, of Funchal, Madeira, commenting upon Dr. D. Morris's exhibition (Nov. 5. 1896) of raphides composed of oxalate of lime in the bulbs of hyacinths, the handling of which had produced a form of eczema. Mr. Johnson mentioned a parallel case in *Richardia æthiopica*, a beautiful aroid known to gardeners as the Lily of the Nile. The laundresses at Funchal had tried to utilise the starch obtainable from the corms, but complained of the irritation in the hands produced by it, which, on examination, was found to result from the presence of numerous needle-shaped raphides, as in the case of the hyacinth-bulbs referred to.—Dr. G. Elliott Smith read a paper on the origin of the *Corpus callosum*: a comparative study of the hippocampal region of the cerebrum of marsupialia and certain cheiroptera.—On behalf of Dr. J. Gilchrist a paper was read on the minute structure of the nervous system of the mollusca.

EDINBURGH.

Royal Society, January 18.—Sir Arthur Mitchell in the chair.—Dr. John Murray read a paper on the Ocean Ranger Reef of the South-west Pacific. This was a reef which the ship *Ocean Ranger* had reported encountering in lat. 88° 44′ S., long. 157° 2′ E., and desired to have marked as dangerous to navigation. The *Penguin*, under Commander Balfour, was sent there, but could find no reef that would be dangerous. The very careful soundings which were then taken had an interest of another kind. They revealed the presence of a huge pinnacle reaching to within 837 fathoms of the surface, and sinking to 1800 or 1900 fathoms at the base. A coloured map and section, which showed that the pinnacle had a crag-and-tail shape, were submitted for inspection. At the highest point, the soundings showed 85 per cent. of calcium carbonate, and 65 per cent. at the lowest. From the nature of the fragments found in the soundings the rock was evidently of volcanic origin, and it was being disintegrated by the action of the sea.—Dr. Murray then read a paper on the physical conditions of the ocean to the east of the Australian continent. Of recent years great additions had been made to our knowledge of this part of the ocean, due to the careful surveys of Government ships. He had examined over 2000 soundings sent him from time to time by the hydrographer. After reviewing the physical and geographical features of this region, Dr. Murray said that the most interesting point was the reading of the deepest ocean sounding yet taken. Before this, 4600 fathoms had been found off the coast of Japan, and an American boat had gone some 70 fathoms better; but Captain Balfour had found a depth of 5155 fathoms east of the Kermadec Islands. The inference to be drawn from this and other data, taken together, was that we had here the remains of a continent that had sunk beneath the waves. Speaking next of the temperature of this part of the ocean, he said that the heated waters of the equator, and north of it, were driven by the prevailing wind to this part, where they formed a huge whirl like the Saragossa Sea. At 100 fathoms under the surface near the equator the highest temperature for the whole ocean was recorded; and all over, throughout the year, the temperature never fell below 70°; and hence Prof. Dana's condition for the formation of coral was fulfilled. There was more coral here than anywhere else. Speaking of Falcon Island, which at one time was several miles in extent and from 250 to 290 feet high, he remarked that in 1896 it was a black line upon the surface, surrounded by shoals. What had happened accorded with his own idea of coral-reef formation, which he had arrived at many years ago, and had since seen no occasion to change. The bottom temperature in the centre was 36° after 1500 fathoms. The water in the deep and wide gullies was colder than in the centre. Dr. Murray then briefly described the distrbution of products in this region. Calcium carbonate was the principal. At depths less than 100 fathoms it occurred in the percentage of 80 or 90, while it ranged between 50 and 70 for depths down to 2400 fathoms. Then it disappears very rapidly till 3000 fathoms is reached, and there is no trace of it in the lowest soundings. Further south there was more detrital matter, and it was more chalk-like in appearance. Nearly every kind of deposit was represented, though there was very little Regillarian ooze. The carbonate of lime disappeared at a less depth in extra-tropical regions than in tropical.—Dr. C. G. Knott made a brief note, introducing a second series of investigations into magnetic strains. He had set himself to discover how much of the changes already described was due to change of length and how much to change of width, and he exhibited graphs of the relations of these.—Prof. Tait read a paper on the physical properties of the electromagnetic medium. He developed the consequences of the hypothesis that the connection between the electric and magnetic vectors in Maxwell's equations may be due to the fact that they are not directly disturbances in the ether, but concomitants or results of the disturbance; just as the condensations and rarefactions of the air, which affect the drum of the ear, are concomitants of the displacements of the air.—Papers by Lord

Kelvin, on osmotic pressure against an ideal semi-permeable membrane, and on a differential method for measuring differences of density and of vapour pressure of solutions, were also read (see pp. 272–3).

DUBLIN.

Royal Dublin Society, December 16, 1896.—Mr. Thomas Preston in the chair.—The following papers were presented:—The geographical distribution of dragon-flies, by Mr. G. H. Carpenter.—A suggestion as to the origin of the canals of Mars, by Dr. J. Joly, F.R.S. The formation of the principal curved lines and double "canals" observed by Prof. Schiaparelli and Mr. Lowell is referred by the author to the disturbances of the crust of the planet produced by the gravitational attraction of small satellites in past times rotating close to the surface. It is shown that a satellite so small even as Phobos, if rotating some 50 or 60 miles above the surface, would produce very appreciable stresses in the surface crust of the planet. Integrating the horizontal component of the gravitational pull outwards from beneath the satellite, a ring of maximum stress defined as the base of a cone having the satellite at its summit and a semi-angle of 71°, is obtained. If the satellite is moving relatively to the surface of the planet, tangents to this circle in the direction of motion define parallel lines of probable rupture. There is also probable development of a central line of weakness vertically beneath the satellite's line of motion. These disturbances probably gave rise to mountain ranges—possibly of small altitude—which constitute the "double canals" and lines observed on the surface. Mountain ranges more readily explain the seasonal changes in visibility than any other hypothesis as to their nature. Satellites rotating so close to the surface will probably exist only for a score of years, or thereabouts, between such limits of distance as 70 to 50 miles, when, sinking deeper into the planet's atmosphere, their energy will be rapidly absorbed, and they will fall in; assuming as most probable that the day is longer than the month, or that the satellite's motion is retrograde. The intersection of the radius vector of the satellite with the surface of the planet will describe certain curves, the span of which upon the equator will depend upon the rates of relative angular velocity of planet and satellite. Given the span and rise, the curvature is completely defined. The curves upon Mr. Lowell's map, and those given by Prof. Schiaparelli, are apparently in close agreement with the theoretical curves. They are not great circles. It is shown that nodal points will give rise to centres of radiating lines. The location of Mars' orbit so close to the ring of asteroids—some of which are known to come within his mean distance from the sun—is considered to render *à priori* probable the assumption that Mars has throughout the past at intervals picked up satellites which, after describing a spiral path round him, ultimately fell in. Phobos is—according to lunar theory—probably in the way to do so at some future time. It is shown that a small solid satellite, even if composed of no stronger material than basalt, will be amply stable under the unbalanced gravitational and centrifugal forces to which it will be subject when close to Mars' surface.—An account of some experiments to determine the exact position from which the X-rays emanate in a focus tube was given by the Right Rev. Monsignor Molloy.

PARIS.

Academy of Sciences, January 25.—M. A. Chatin in the chair.—The President presented to M. Faye the medal struck on the occasion of the fiftieth anniversary of his nomination to the Academy, and gave a review of his contributions to Astronomy.—Verbal report on the contents of a sealed letter, opened at the request of the heirs of the late M. B. Heire; and relating to several questions in surgery, by M. le Dr. Guyon.—Note on a screwbrake, with vertical action on the rail, by M. G. Camps.—On two errata in the "Œures de Gauss," by M. Schering.—Photography of an extraordinary protuberance, by M. H. Deslandres. An account of a solar protuberance photographed at the Observatory of Paris on May 31, 1894, which attained the enormous height of 10′23″ of arc, or one-third of the solar diameter.—On the first integrals of dynamics and on the problem of n bodies, by M. P. Painlevé.—On the expansion of nickel steel, by M. C. E. Guillaume. By comparison with a platino-iridium bar, the expansion of which had been carefully studied, the expansion of nickel steels was found to be anomalous, in the sense that instead of following approximately the law of mixtures, the expansion was even higher than bronze. To further elucidate this point, the expansions of a series of nineteen bars were determined, in which the proportions of nickel varied from 0 to 100 per cent. The coefficient of expansion reaches a maximum at about 24 per cent. of nickel, and rapidly falls until a minimum is reached at 36 per cent. of nickel, after which it slowly increases until the original value is obtained.—Fluorescence of vitrified materials, under the action of the Röntgen rays, by M. Radignet. By the use of screens of glass (especially the glass from the manufactory of Saint-Gobain, called *crystal*), enamel, or porcelain instead of the usual ones of cardboard covered with fluorescent crystals, the images obtained are less brilliant, but more sharply defined.—On an absolute electrometer designed to measure small differences of potential, by MM. A. Perot and C. Fabry (see p. 327).—An optical apparatus by which objects cast or engraved can be seen in relief and in their normal position, by M. Ernest Moussard.—On the determination of the ratio of the two specific heats of acetylene, by MM. G. Maneuvrier and J. Fournier. The method of Clement and Desormes was used, the flask employed holding fifty litres. It was found that the acetylene obtained by the action of water upon calcium carbide was by no means pure, only 94 per cent. of it being absorbed by ammoniacal cuprous chloride. The system of purification adopted reduced this to less than 0·5 per cent., and the gas thus obtained was found to have lost its allicaceous odour, held up to the present to be one of its characteristic properties, although still possessing a strong penetrating odour. The value found for $\frac{C}{c}$ was 1·273.—The physical, physiological, and therapeutic effects of rapidly alternating currents, by M. Boisseau de Rocher.—Action of carbon monoxide and dioxide upon aluminium, by MM. Guntz and Masson. At a high temperature, in the presence of a little iodide or chloride of aluminuim, aluminium is readily burned in a current of either CO or CO_2. With the former the reaction is

$$6Al + 3CO = Al_2O_3 + C_3Al_4,$$

the aluminium carbide giving practically pure methane on boiling with water. Carbon dioxide gives the same product.—On the phosphides of chromium and of manganese, by M. A. Granger. By the action of phosphorus vapour upon the chlorides of chromium and manganese, the phosphides CrP and Mn_3P_2 were obtained.—Spectra of the metalloids in their fused salts, silicon, by M. A. de Gramont.—Influence of temperature upon the rotatory power, by M. P. A. Guye and Miss E. Aston.—On two isomeric triethylene-diphenylhydrazines, by M. H. Causse.—On a superior homologue of urea, by M. Oechsner de Coninck. The substance has the composition $C_4H_{16}N_2O$, and was obtained from the urine of a person suffering from alcoholism.—New researches on the embryonic nervous system of the Crustacea, by H. Nicholas de Zograf.—On the histology and microscopical anatomy of the encephalon in fishes, by M. Catois. The results obtained by the use of methylene-blue as a staining reagent are entirely confirmatory of the researches of R. Cajal.—On the biology of *Dendroctonus micans* (Ratz), by MM. A. Menegaux and J. Cochon.—On the pseudo-larval pairing of some *Sarcoptidæ*, parasitic in the domestic pigeon, by M. S. Jourdain. The species studied were *Ptérolichus falciger*, *Dermoleichus asternalis*, and *Pterophagus strictus* (Mégnin).—Phenomena of autotomy observed in the goubs of *Monandroptera inunicans* and *Raphiderus scabrosus*, by M. Edmond Bordage.—On the gases given off in water by metallic carbides, by M. E. Maumené.

SYDNEY.

Royal Society of New South Wales, September 2, 1896.—Mr. J. H. Maiden, President, in the chair.—Papers read:—Note on recent determinations of the viscosity of water by the efflux method, by G. H. Knibbs—Current Papers, No. 2, by H. C. Russell, F.R.S.

October 7.—On the occurrence of precious stones in New South Wales, with a description of the deposits in which they are found, by Rev. J. Milne Curran. The Society's bronze medal and money prize of 25*l.* were awarded to the writer of this paper—On the constituents of the sap of the "silky oak" *Grevillea robusta*, R.Br., by Henry G. Smith.

November 4.—On sill structure and occurrence of fossils in eruptive rocks in New South Wales, by Prof. T. W. E. David.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 4.

ROYAL SOCIETY, at 4.30.—On the Condition in which Fats are absorbed from the Intestine: B. Moore and D. P. Rockwood.—The Gaseous Constituents of certain Mineral Substances and Natural Waters: Prof. W. Ramsay, F.R.S., and M. W. Travers.—Some Experiments on Helium: M. Travers.—On the Gases inclosed in Crystalline Rocks and Minerals: Prof. Tilden, F.R.S.—Meteorology of India during the past Five Years in Relation to the present Scarcity in India: J. Eliot, F.R.S.—On Lunar Periodicities in Earthquake Frequency: Prof. Knott.

ROYAL INSTITUTION, at 3.—Some Secrets of Crystals: Prof. H. A. Miers, F.R.S.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

LINNEAN SOCIETY, at 8.—A Revision of the Tribe Naucleæ (Nat. Ord. Rubiaciæ): Dr. G. D. Haviland.—A Contribution to the History of New Zealand Echinoderms: H. Farquhar.

CHEMICAL SOCIETY, at 8.—The Oxidation of Nitrogen: Lord Rayleigh.—Researches in the Stilbene Series, I.: Dr. J. J. Sudborough.—Diortho-substituted Benzoic Acids, III.; Hydrolysis of Substituted Benzamides: Dr. J. J. Sudborough, Percy G. Jackson, L. L. Lloyd.—Apparatus for Steam Distillation: Dr. F. E. Matthews.—Oxidation of Sulphurous Acid by Potassium Permanganate: T. S. Dymond, F. Hughes.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.30.—Fourth Report to the Alloy Research Committee: Prof. W. C. Roberts-Austen, C.B., F.R.S.

CAMERA CLUB, at 8.15.—Flying Machines and Automatic Guns: Hiram Maxim.

FRIDAY, FEBRUARY 5.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.30.—Partially-immersed Screw Propellers for Canal Boats, and the Influence of Section of Waterway: Henry Barcroft.—Mechanical Propulsion in Canals: Leslie S. Robinson.

SCIENCE AND MORALITY.—IN THE YEAR 2000.

Science et Morale. Par M. Berthelot. Pp. xii + 515. (Paris: Calmann Lévy, 1897.)

THOSE who wish to gain some idea of the spirit animating scientific workers in France at the present day may study with advantage this new proof of the inexhaustible energy of the marvellously versatile perpetual Secretary of the Academy of Sciences. The book is for the most part a collection of essays on biographical, educational, historical and philosophical subjects, together with addresses, letters, and speeches on similar matters; although of unequal interest and importance, these will in many cases more than repay careful perusal and examination.

It is the work of a very remarkable man—one of the most remarkable of our time—who describes his own career most truly when he says:—

"Depuis cinquante ans, je recherche les connaissances des choses avec une curiosité et une sympathie infinies."

Infinite curiosity and infinite sympathy—although both qualities that should characterise all scientific workers—are too seldom sufficiently developed in one individual, the latter especially being often strangely absent: the study of a man in whom such qualities are conjoined is therefore interesting in many ways, and becomes the more so as the conviction grows that he is a striking example of a type of mind altogether rare.

A student in his laboratory during the earlier years of his life, since 1870, when the desire to serve his country in the hour of her great need led him to enter the public service, he has taken part in the work of national defence, of public instruction and of general politics, attaining recently to the high rank of Minister of Foreign Affairs—besides continuing with unremitting ardour the researches which have made his name famous throughout the scientific world.

The first to show that the natural fats could be artificially prepared from acids and glycerol; the first to study the great group of vegetable oils, the turpentines, scientifically; the first to establish (in 1859) the existence of acetylene as a definite compound, and the discoverer of the method of producing it directly from carbon and hydrogen: of late years he has devoted his attention chiefly to thermochemical inquiries, and has rendered lasting service especially by the invention of the calorimetric bomb—one of the most ingenious instruments of scientific research ever devised.

Moreover, recognising that

"En toutes choses, c'est en remontant aux origines que l'on arrive à mieux comprendre l'état présent,"

he has devoted himself with surprising assiduity also to the study of ancient Arabic, Greek and other writers from whom information could be gleaned of the history of scientific discovery.

The ultimate predominance of science in all human affairs is the key-note sounded throughout the volume this being carried in the final essay to a point beyond which even writers of fiction have scarcely dared to travel.

"La science domine tout: elle rend seule des services définitifs. Nulle homme, nulle institution désormais n'aura une autorité durable, s'il ne se conforme à ses enseignements!"

These, the closing words of the preface, are words of indubitable truth; yet how few there are who will thoroughly appreciate their importance and significance—who will understand the *full* meaning of the word science: were it appreciated at all generally, how much more might be accomplished even with our present imperfect means! The conviction that such is the case should at least lead us to do our utmost to make the doctrine intelligible and popular; and to this end attention may be drawn to M. Berthelot as a most powerful and engaging witness.

"La Science et la Morale," the opening chapter in the book, is a vigorous and eloquent essay in which the thesis is maintained that morality has no other basis than that which science furnishes: that progress, past and present, of morality, both in the case of individuals and of society, has been and always will be correlative with the progress of science. Frankly hostile to all theories of the divine origin of moral laws, M. Berthelot, in fact, is the outspoken advocate of the view that man is himself the source of morality.

"L'homme trouve la morale en lui-même et il l'objective en l'attribuant à la divinité."

And a determined enemy of the ecclesiastical spirit, although less militant and incisive perhaps, he insensibly reminds us in many ways of Huxley—both having the same object in view and the same hatred of false pretence and unscientific method.

The next essay of importance, entitled "La Science Educatrice," written apparently in 1891, deals with the crisis in secondary education consequent on the revolution going on in France as elsewhere against an exclusively classical system, and in favour of the introduction of science as a necessary element. Although the arguments used are very largely those with which we are familiar, being presented with the literary grace peculiar to the skilful French writer, the article is one that may be read with pleasure as well as studied with profit. The history of secondary education in France is sketched in a most interesting manner, and the many faults of the present system are clearly recognised and pointed out, as well as the reasons for instituting changes.

M. Berthelot, of course, insists that scientific studies should be made correlative with other studies from the outset. He also dwells on the capital importance of science to the moral as well as the intellectual education of humanity.

"L'habitude de raisonner et de réfléchir sur les choses, le respect inébranlable de la vérité et l'obligation de s'incliner toujours devant les lois nécessaires du monde extérieur, communiquent à l'esprit une empreinte ineffaçable. Elles l'accoutument à respecter les lois de la société, aussi bien que celles de la nature, et à concevoir les droits et le respect d'autrui comme une forme même de son propre droit et de sa propre indépendance personelle."

It is noteworthy that M. Berthelot is in agreement with those of us who hold that our children—especially girls—are too frequently subject to severe over-pressure owing to the multiplicity of subjects they are forced to study at school.

"A surcharger l'esprit des enfants par l'acquisition réelle ou prétendue de tant de connaissances diverses, on risque de le fatiguer avant l'heure et d'en empêcher l'évolution normale. On ruine en même temps la santé à l'age du développement physique ; risque plus marqué encore pour les jeunes filles que pour les jeunes garçons."

And he also corroborates the view that great injury is often done by preparation for examinations. Thus, speaking of those who are preparing to compete for admission into higher schools, such as the École polytechnique, he writes :—

"Tandis que les candidats futurs s'y consacrent tout entiers, souvent avec un effort excessif qui épuise leur santé, ils abdiquent leur individualité et, absorbés par le mécanisme de la préparation, ils perdent, eux aussi, la curiosité et l'amour de la réflexion originale."

Would that this doctrine could be brought home to, and made popular with, our Indian Civil Service Commissioners and other such examining bodies. Perhaps the country will some day realise what price it has paid for the destruction of nepotism, even if it do not question the efficacy of the method it has adopted ; and at least we may hope that in times to come, medical men will respect the injunction, "Physician, heal thyself," after recognising the injury that is done by over-study to the mental powers of students qualifying to join the profession. But those will be days when true morality will have a place in education because true science has found a place in it.

"La haute culture et la loi militaire" is an interesting report of speeches delivered in the Senate in 1888–89, which were directed against the introduction of a law making three years' military service compulsory on all classes, and favouring the limitation of service to a much shorter period in the case of the student class, who are pictured as the backbone of the community. In the course of this debate M. Berthelot made the interesting statement that he is the grandson of a village farrier.

The biographical sketches in the volume include graceful notices of Pasteur, Claude Bernard, Paul Bert, and F. André.

In a charming account of the doings of a colony of ants which he had sought to dislodge, M. Berthelot displays himself as an ardent naturalist observer as well as psychologist ; but it is not the first time that he has appeared in such a character—indeed, he tells us that he has for years past made these remarkable insects the subject of careful study.

The historical essays printed in the latter part of the volume are good examples of his style and versatility : that on the discovery of alcohol and of distillation, as well as that on the origin of chemical industries, may be specially commended to chemists as being full of interest ; the essay on Papin is an eloquent attempt to do further justice to the memory of one for whom a capital share in the invention of the steam-engine may be claimed.

Very appropriately, as emphasising the point of view taken throughout the work, M. Berthelot publishes, as the last chapter in the volume, a speech delivered in 1894, in which a fanciful sketch is given of the changes that it may be expected will have been brought about at the close of another century—in 2000—through the introduction of science into all our affairs :—

"Dans ce temps-là, il n'y aura plus dans le monde ni agriculture, ni pâtres, ni laboureurs : le problème de l'existence par la culture de sol aura été supprimé par la chimie ! Il n'y aura plus de mines de charbon de terres, ni d'industries souterraines, ni par conséquent de grèves de mineurs ! Le problème des combustibles aura été supprimé par le concours de la chimie et de la physique. Il n'y aura plus ni douanes, ni protectionnisme, ni guerres, ni frontières arrosés de sang humain ! La navigation aérienne, avec ses moteurs empruntés aux énergies chimiques, aura relégué ces institutions surannées dans le passé ! Nous serons alors bien prêts de réaliser les rêves du socialisme . . . pourvu que l'on réussisse a découvrir une chimie spirituelle, qui change la nature morale de l'homme aussi profondément que notre chimie transforme la nature matérielle !"

It is suggested that we shall have tapped the central fires of the earth, and thence derive our supplies of energy, and that we shall live on tabloids artificially prepared. As a modest picture of the chemist's potential activity, the sketch is perfect, and it is unfortunate that it is necessary to introduce so important a *pourvu que* in order to keep expectation within due bounds ! M. Berthelot is even a little inconsequent, and forgets, perhaps, that in an earlier address on the place of science in agriculture he paints a somewhat different picture and, perhaps, a nobler one :—

"Or nul idéal n'est supérieur a celui de l'agriculture. La vie des champs est le type normal de la vie humaine. Là seulement, l'homme se développe en toute plénitude. La vie des champs favorise à la fois la santé matérielle des corps et la santé morale de l'esprit. Le paysan robuste, laborieux et intelligent, a toujours fait la force des nations."

If agriculturists are thrown out of employment by the disappearance of agriculture, what are they to do ? All cannot engage in the manufacture of compressed food in the synthetical laboratories which will supersede Nature ; and besides this to waste solar energy in the manner implied would be unscientific. Moreover, even the most ardent evolutionist will require more than one hundred years to reduce the stomach of the city alderman to such dimensions that a few wafers of nitrogenous and carbohydrate materials will suffice to produce in it the effect of a full meal, even if fed besides with speeches of inordinate length and dulness.

But closely as he enters into competition with Jules Verne, in the course of his "excellent fooling," M. Berthelot does not venture to look across the water and comfort us with the assurance that in the year 2000 we shall have a Minister of Education whose interest in the subject will be in some measure comparable with that of his distinguished French predecessor of a century before, and that there will be a true university established in London in which all branches of science and morality will consort and prevail in place of examinations and narrow-mindedness. No doubt he desired to draw the line at the probable. H. E. A

A STUDENT'S COURSE OF ASTRONOMY.

Cours d'Astronomie. Par M. B. Baillaud. Two vols. Pp. 280 and 509. (Paris: Gauthier-Villars et Fils, 1896.)

IT is a remarkable but no less accurate statement to say that the English student who wishes to dive deep into the inner circle of astronomical science must be dependent to a great extent on works produced outside this country. Oppolzer, Chauvenet, Watson, Klinkerfues, Olbers, and many others are books with which the serious reader must become well acquainted, to say nothing of works of a more advanced type, such as those by Tisserand, Gyldén, &c.

Our literature deals, for the most part, with descriptive astronomy, in which the sun, moon and planets, &c., are lavishly described and illustrated: of these there is no limit. We are also well supplied with works on physical astronomy, but this branch of science is not included in the above remarks.

In the two volumes before us, which we owe to the director of the observatory at Toulouse, M. Baillaud, we have an excellent course of astronomy for students. This work is not one devoted to descriptive astronomy, nor a treatise on celestial physics, but a mathematical course, presenting the reader with a survey of the various problems and modern methods of astronomy, including some of the more important results which have been obtained.

In a brief and yet not too concise a manner, the author has brought together all the essential points that are necessary for a course in astronomy without extending any of them disproportionally.

The first volume, we find, was published in the year 1893. In this some of the theories applicable to the study of experimental science are handled, the knowledge of which is as important to physicists as to astronomers. Thus the author discusses the principles of the calculus of probabilities, showing how they may be applied to the theory of the errors of observation: the method of solving equations by the method of least squares is also here referred to in full. Next in order comes the general theory of optical instruments, which is investigated at some length, followed by the descriptions of the principles and problems involved in the action of lenses, prisms, eyepieces, various kinds of telescopes, &c. In the chapter on the different kinds of instruments used in making observations, chronometers, pendulums, levels and verniers are first in some detail described before the actual instruments, such as the meridian circle, equatorial, altazimuth, &c., are dealt with. The equatorial coudé comes in for a good description, and, like the others, is well illustrated. The last two chapters are devoted to the various methods of angular measurement, including the trigonometrical formulæ for facilitating the solutions of spherical triangles, and to the formulæ for interpolation as suggested by the works of such men as Newton, Legrange, Gauss, and Jacobi.

The second volume, which has only recently been published, contains as many as 500 pages, and may be considered the more important part of the work.

The first few chapters are devoted to the solution of such problems which may be considered here as preliminary to the main question of orbit determination. These include such subdivisions as systems of coordinates, refraction, parallax, aberration, precession, &c., each of which M. Baillaud has expounded with clearness and in sufficient detail to enable the reader to understand them. The apparent movements of the sun, together with those of the major planets, are next handled, the author discussing the various peculiarities of these motions, and how some of them may be dependent on the movements of the earth. This leads him naturally to deduce the laws of motion from observation, eventually leading up to the problem of orbit determination.

The chapter dealing with the methods of computation adopted at the present day for the determination of the orbits of comets, planets, &c., will be found expounded in a manner that is very helpful for the student. The author has kept strictly in view the main line of thought in the solution of the various problems, and has not overwhelmed the reader with the presence of too much detail on comparatively minor points. In this respect the student is at an advantage; but, wherever necessary, he can always refer to that classical work of Oppolzer for further inquiry into minor details on any special question.

In the chapter on perturbations, all the three well-known methods, which we owe to Bond, Encke, Hansen, and Tietjen's modification of the last-mentioned, have been dealt with in a similar manner.

The movements of the moon and of Jupiter's satellites are next the subject of discussion, after which attention is devoted to the form and dimensions of the earth, a description being given of the various instruments and methods employed in such determinations. In addition to other problems, those relating to eclipses are referred to at some length; while the last chapter professes to give a brief summary of what is termed modern astronomy. This latter is found to be very scanty indeed, and is likely to do a student more harm than good. The lack of references of any kind, and the numerous omissions of importance are not likely to inspire confidence. In a future edition it would be advisable either to make this part more complete, and add to its usefulness by abundant references; or, on the other hand, omit it entirely, as it is quite unnecessary in a book of this kind.

In the above notice, only a brief survey of the contents of these volumes has been made. It must be understood, however, that the author has dealt with several other problems of minor importance, their solutions being conspicuous by the conciseness of the methods employed.

To sum up in a few words, the work as a whole may be said to form a serviceable contribution to the student's library. Not only will it be used by those for whom it is specially intended, but English students, and especially those unacquainted with the German language, will find it an important help in their work.

The text is relieved throughout by the insertion of many figures and woodcuts.

OUR BOOK SHELF.

Register of the Associates and Old Students of the Royal College of Chemistry, the Royal School of Mines, and the Royal College of Science. Edited by Theodore G. Chambers, Assoc.R.S.M. Pp. cxxii + 231. (London: Hazell, Watson, and Viney, Ltd., 1896.)

THIS Register contains the names and short biographical notices of many hundreds of the past students of the three institutions, the history of which has been so closely interwoven. Much praise is due to Mr. Chambers, and those who have assisted him, for the care and patience with which man after man has been tracked down and run to earth, that he may yield a few lines of print to this book. A glance over its pages cannot fail to be gratifying to any old student, for it is at once apparent how much the pure sciences, as well as Mining and Metallurgy, owe to the men who have been trained at these colleges. Such names as those of De La Rue, Odling, Frankland, Armstrong, Tilden and Abel among chemists; of Mathiessen, Roberts-Austen, Bauerman and Gilchrist among metallurgists; of Judd, of Le Neve Foster, and of the Blanfords, are indissolubly linked with the history of the sciences which they respectively represent. But besides these, on almost every page of the Register the names occur of men, Fellows of the Royal Society and others, of whom any college or university might well be proud.

The history of the united schools, which is also given, clearly shows their continuous growth from their foundation up to the present time, and the biographies and excellent portraits of the past and present professors will be highly valued by their old students as interesting mementos of those who have largely influenced and directed the course of their lives.

Fruit-Culture for Amateurs. By S. T. Wright. With an Appendix on Insect and other Pests injurious to Fruit Trees. By W. D. Drury. Pp. 244. (London: Upcott Gill, 1897.)

THE culture of hardy fruits has received a great impetus of late years from the depressed state of agriculture, whilst the enormous importations from America and from France have at length enabled our cultivators to realise the consequences of their own neglect.

It might be supposed that a market thus captured by the foreigner would never be regained; but there are signs that this is not so. Our home-grown supplies, to a large extent, come at a season when foreign competition is least active. English-grown apples, properly marketed, are the finest the world produces, and command the highest prices. Plums can be grown here so well and so abundantly as to effectually neutralise competition. Small fruits—under which category are included strawberries, raspberries, gooseberries, &c.—do not pay for long carriage, a point in favour of the British cultivator. The culture of grapes under glass has also increased to such an extent that lately it has been found profitable to export them even to the United States. All this shows that fruit-culture is extending, and that when carried on in a business-like way it returns a fair amount on the capital invested and the labour expended. The little book before us is specially intended for amateurs; but it contains just the sort of information which the novice in fruit-culture for market requires. It is the work of an experienced practitioner in whom the reader may place the fullest confidence. In this place we need not enter into cultural details; but it is instructive to note throughout Mr. Wright's pages, whether he be treating of apples or of figs, of strawberries or of medlars, how identical are the general principles of cultivation.

Mr. Wright had no intention of dealing with physiological matters—his aim is entirely practical—and yet we find throughout the general principles brought into prominence, unconsciously, perhaps, on the part of the author, but still manifestly so to the amateur reader. This is a great advantage to the book. Amateurs now-a-days know that no progress can be expected in practical arts unless the practitioner has some knowledge of the principles on which they are based. This is only another way of saying that a man must know his business before he can hope to succeed in it. Mr. Wright's book will greatly help the reader to this knowledge, and may be recommended accordingly.

The Appendix, by Mr. Drury, occupies nearly as much space as the chapters of the book. It is devoted to a description of the principal noxious insects and fungi, and is interesting as showing that, somewhat tardily perhaps, our cultivators are realising the advantages of "spraying," a detail in which our American cousins have got the start of us.

Annuaire de l'Observatoire Municipal de Montsouris, pour l'Année 1897. Pp. xii + 664. (Paris: Gauthier-Villars et Fils, 1897.)

THE Montsouris Meteorological Observatory was established by M. Duruy in 1871, by the influence of Dumas then president of the Municipal Council of the City of Paris. The work carried out in it is divided into three principal sections, which, while including purely scientific researches, take in also subjects relating to the climatology and hygiene of Paris. The first branch of the Observatory's work belongs to physics and meteorology, among the subjects included in this section being:—atmospheric electricity, the usual meteorological observations, the influence of smoke and vapours upon atmospheric variations, &c. The chemical work done at the Observatory refers to the variations in the composition of air in different parts of Paris, analysis of water, variations in the composition of sewage waters and of the Seine at different points, and methods of filtration. To the micrographic section of the Observatory is entrusted not only bacteriological statistics, and the determination of the meteorological conditions which affect the abundance of micro-organisms in air, soil, and water, but also the examination of the specific characters of bacteria. A bacteriological laboratory for the diagnosis of diphtheria, and of other diseases of which the active principles are known, was joined to the micrographic section of the Observatory at the beginning of last year, and has been found of great service to the public and to medical practitioners.

A large amount of valuable information on these and many other matters is given in this *Annuaire*. Meteorologists, bacteriologists, and students of public health will be particularly interested in the volume.

Essays of George John Romanes. Edited by C. Lloyd Morgan. Pp. 253. (London: Longmans, Green, and Co., 1897.)

BY collecting and republishing these essays, Prof. Lloyd Morgan has carried out a wish of Romanes, and at the same time has given general readers of science a very interesting volume. The subjects of the essays here reprinted from various magazines and reviews are:—primitive natural history, the Darwinian theory of instinct, man and brute, mind in men and animals, origin of human faculty, mental differences between men and women, the object of life, recreation, hypnotism, hydrophobia and the muzzling order. Such an attractive selection from the writings of a master-mind like Romanes, should appeal successfully to a wide circle of readers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Direct Cynthesis of Optically Active Proteid-like Substances

IN a recent communication to the Royal Society (*Proceedings*, No. 364, lx. 337-349), of which an abstract has appeared in NATURE, Dr. Pickering describes experiments he has made—in extension of those carried out by Grimaux several years ago—on the synthesis of certain proteid-like substances: the substances were obtained by heating amido-acids, such as par- and meta-midobenzoic acid and tyrosine, with amides, such as alloxan, biuret and xanthine, in presence of a dehydrating agent, or even by heating the amido-acid alone with the dehydrating agent. The substances so produced are said to be all soluble in warm water, forming opalescent *lævorotatory* solutions, the values given for α_D varying between -38 and -52; but it is not clear what is meant by this, as the symbol α_D is commonly used to denote the observed rotatory power, and is meaningless unless the strength of solution, &c., be stated, from which the specific rotatory power can be deduced.

Dr. Pickering does not appear to be aware that if his statements are correct, he has made a discovery of a startling character, altogether remarkable in the light of our present knowledge. In all cases hitherto studied—not excluding nitrogen compounds (*e.g.* artificial conine)—as Pasteur foresaw would doubtless be the case, optically active substances are never directly produced; the synthetic product is always inactive. For example, when tartaric acid is synthesised, a mixture is obtained consisting of mesotartaric acid—the internally compensated modification—and racemic acid, this latter being resolvable into equal quantities of the two equally but oppositely active tartaric acids.

It is therefore desirable that Dr. Pickering should state exactly what is the evidence on which he relies as proving that the substances he has obtained are possessed of optical activity. Having reason to think that nitrogen may manifest peculiarities hitherto unsuspected, I await such information with impatience.

Dr. Pickering speaks of having obtained several of the substances in translucent yellowish plates. What are we to understand from this? It would be interesting if we knew whether the substances are crystalline.

Grimaux, who has discussed coagulation phenomena in a thoroughly scientific manner, has pointed out that the proteids do not differ as colloids in any essential manner from mineral and other colloids such as Graham investigated; and it is perhaps, therefore, fair to question whether the production of intravascular coagulation, on which Dr. Pickering lays stress, is so significant a property as he supposes as indicating affinity with true proteids. The substances he has obtained cannot well, from the chemical point of view, bear any real structural relationship to natural proteid substances.

HENRY E. ARMSTRONG.

Carbon in Bright-Line Stars.

DR. HUGGINS should verify his references; it has taken me some considerable time to find the article he erroneously states to be contained in vol. xlviii. of NATURE.

That article was an attempt to summarise a good deal of work I had communicated to the Royal Society, with all necessary details.

To avoid the necessity of giving these details in the article, I distinctly stated that "in the Bakerian lecture for 1888 I gave a complete discussion of the spectra of bright-line stars," and referred to the "bright fluting of carbon which extends from 468 to 474."

The details were thus stated in my communications to the Royal Society:—"The bright band, with its maximum at 468, is the bright carbon fluting commencing at 474, and extending towards the blue with its maximum at 468, as photographed at Kensington" (*Roy. Soc. Proc.*, vol. xliv. p. 37, March 1888).

"It is necessary to state that the maximum luminosity of the blue band, under some conditions, is at about 468. As I have so often had occasion to refer to this, I here reproduce one of the many photographs of the spectra of carbon compounds which show it" (*Roy. Soc. Proc.*, vol. xlv. p. 169, November 1888).

In a paper communicated to the Royal Society, on November 9, 1889, in which this blue band of carbon is very frequently referred to, both in connection with comets and bright-line stars, its position is throughout defined by the figures 468-474, whether the brightest part was at 468 or 474. I had previously shown that the maximum might be at either wave-length in the spectra of different comets, and my earlier papers had sufficiently stated that in the case of bright-line stars the modified band, with the maximum at 468, was in question. Thus in comparing the spectra of comets and bright-line stars, "468-474" was used as a short title for the blue band, whether in flame, comet, or star, and this applied also to the new observations which were recorded at the same time, showing the coincidence of the star band with the spirit-flame band. With the instrument employed, the whole group in the flame spectrum appears as little more than a broad line; but that the previously noted shift of the maximum to 468 was simply regarded as ancient history, is shown by sketches in the Solar Physics Observatory note-books, which I shall be glad to show Dr. Huggins, if he cares to see them.

I certainly see no reason to withdraw my assistants' observations of the blue band, but in the article which has given rise to this discussion (NATURE, January 28, 1897) I regarded them as superseded, as most of Dr. Huggins' observations have been, by recent observations, made with much greater optical means. I am not aware that it is customary to formally withdraw *observations* which have simply been superseded with the help of improved instruments.

I retained the observations of the green fluting, however, for reasons sufficiently stated in my article.

Dr. Huggins apparently objects to my statement that Prof. Campbell does not discuss the origins of the lines and bands which he has measured, but it will be seen by his quotation from Prof. Campbell's paper that my statement is amply justified. Prof. Campbell makes only a general reference to the question of origins, and has only compared with "well-known artificial spectra." It is not quite clear what is meant by "well-known" spectra, but presumably it is the published tables of lines seen in the arc and spark spectra of the more familiar substances which are meant; these lines, however, would not be the only ones to be expected under the exceptional conditions which exist in a bright-line star. The experimental work on the blue band of carbon is only one indication of the necessity for observing terrestrial spectra under special conditions for such an investigation. It is certainly impossible that the resources of a comparatively young institution like the Lick Observatory can be sufficient to cope with this inquiry into origins.

With reference to Prof. Vogel's observations of the varying position of the maximum of the carbon band, I can only repeat the statement of my regret that I had forgotten them when my paper of 1888 was written. I have nowhere stated that this observer ascribed the blue band in the bright-line stars to carbon, but it is certainly strange he has not done so, since a similar band at about the same wave-length in the spectrum of comets was experimentally demonstrated by him to be probably due to carbon.

It would appear that if Dr. Huggins had done me the honour of reading my communications to the Royal Society, his letter would not have been written. J. NORMAN LOCKYER.

February 9.

Origin of the Cultivated Cineraria.

THE discussion in these pages, rather more than a year and a half ago, upon the origin of the "Cultivated Cineraria," by Mr. W. T. Thiselton-Dyer, Mr. W. Bateson and others, was productive of very considerable interest. It raised in my mind the idea of producing some living evidence on the question; but the unfortunate position is, that certain kinds required for the purpose are not in cultivation. I venture to appeal, therefore, to the readers of NATURE, who were interested in the discussion, and who may visit or live in the Canaries or Madeira, to be so good as to send me any seed they may be able to obtain. It is desirable to have seeds of all the herbaceous species of *Senecio*, without exception. *S. Tussilaginis* I consider important, whatever the facts of origin may have been, and it is necessary to have a new stock of *S. cruentus*. I have already used the material at command, and have made a variety of crosses among four distinct types. The set first in flower was exhibited, on account of its showy features, at a recent meeting of the Royal

Horticultural Society. This cross was between *S. multiflorus* (female) and several colour forms of the "Cultivated Cineraria," embodying certainly two distinct species. No direct evidence on origin has been in this particular experiment obtained, or expected, but the predominating influence of the "Cultivated Cineraria" in this and also in the reverse cross, upon the colour and size of the flower-heads, appears to suggest, I think, a possible predominance of one species over another, in other cases. The crosses to which I have referred, taken together, sufficiently demonstrate an extreme readiness to cross, since every one of the thirteen attempts has resulted in a numerous hybrid progeny, while not one of the several hundreds of plants raised has failed of being a hybrid. The only care taken was to exclude insects, which might have brought pollen from another plant, by means of muslin, and no attention was paid to the pollen produced within the muslin bags. This pollen, on the evidence of nearly five hundred plants, had no effect. From the facility with which these plants cross under cultivation—even the woody *S. Heritieri* with the completely herbaceous kinds—it is likely that they cross also in a state of nature, whenever the opportunity occurs. It would be interesting, therefore, to have information of the relative distribution of the kinds, and to know of all variations. There is no doubt a large field and good motive for exploration in the Canaries, and I should be exceedingly thankful for any seeds or plants that may be sent me.

Botanic Gardens, Cambridge. R. IRWIN LYNCH.

Prichard and Acquired Characters.

PROF. MELDOLA, in his suggestive address to the Entomological Society on January 20, very rightly puts Prichard before Galton and Weismann in the list of those who have formulated the theory that acquired characters are not inherited by offspring. Some years ago, when Platt Ball's interesting little book was published on the question, "Are the Effects of Use and Disuse Inherited?" I was struck by the careful way in which the author pointed out how "so sound and cautious an observer as Francis Galton had also [*i.e.* as well as Weismann], in 1875, concluded that 'acquired modifications are barely, if at all, *inherited* in the correct sense of that word.'" At the same time my memory went back to some allusions I had seen in an old book (Coombe's "Constitution of Man," Edinburgh, 1836, a copy of which I had recently bought at a marine store dealer's for one halfpenny) to the theories of Dr. Prichard. I subsequently looked up the references and made some notes, which have until now been pigeon-holed. I quote three passages and a note as bearing on the question, Who first pointed out that acquired characters are not inherited? ("Researches into the Physical History of Mankind," vol. ii. p. 536, by James Cowles Prichard, M.D., F.R.S.)

"It has often been a question among physiological writers what peculiarities of structure are liable to be transmitted by parents to their offspring, and what terminate with the individual, without affecting the race. Perhaps the following remarks may afford the solution of this difficulty:—

"*On the other hand, changes produced by external causes in the appearance or constitution of the individual are temporary, and, in general, acquired characters are transient; they terminate with the individual, and have no influence on the progeny.*[1] [The italics are mine.]

Dr. Prichard has very properly mentioned the source of his ideas, and it is to be hoped that we also may give credit where credit is due. WILFRED MARK WEBB.

Biological Laboratory of the Essex County Council, Chelmsford, January 27.

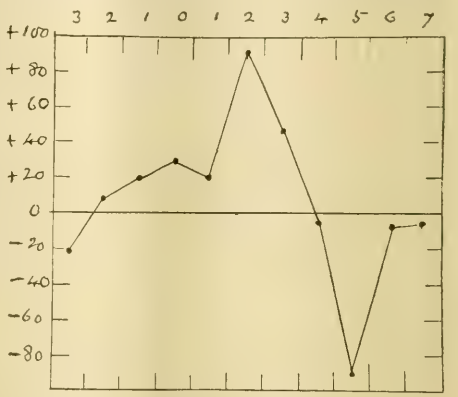
I AM very glad that Mr. Webb has also directed attention to Dr. Prichard's share in the establishment of the doctrine of the non-transmissibility of acquired characters. I should like to add that my attention was first called to the work in question (2nd edition, 1826) by my father-in-law, Dr. Maurice Davis. Prof. Poulton has taken the subject in hand, and is preparing an article on the whole question. R. MELDOLA.

[1] This distinction, which has not been pointed out by any former writer on physiological subjects, was first suggested to me in conversation, many years ago, by Mr. Benjamin Grainger, of Derby."

Rainfall in the Lake District.

THE recent publication, in Mr. Symons' *British Rainfall* for 1895, of fifty years' data of rainfall at Seathwaite (1845–94), affords an opportunity of studying the climate of this very wet district in relation to the vexed question of sunspot influence on weather.

The following might, perhaps, be offered for criticism. Consider each maximum sunspot year, three years before it, and seven after it. (The intervals from maximum to minimum, it is known, are generally longer than those from minimum to maximum.) Indicate the character of each year with a + or − sign, according as it is above or below the average (137 in.). We may further give the algebraic sums of each vertical group, and of certain horizontal groups (*a* to *b*) as shown; and plot in a



Sunsp. Max.	*a*			Max.			*b*				Sums *a* to *b*
	3	2	1	0	1	2	3	4	5	6	7	
1848	+	+	−	+	−	+	+	+	−	+	−	+ 14
1860	−	−	+	+	+	+	+	−	−	+	−	+133
1870	−	+	+	−	−	+	+	+	−*	−	+	+ 29
1883	−	−	+	+	−	+	−	−	−	−	+	+ 27
1893	+	+	−	+	+							+ 5
	−21	+9	+20	+30	+20	+92	+46	−5	−88	−6	−5	

curve the values for the vertical groups. (Should any objection be taken to comparing vertical groups of four members with those of five, I may say that exclusion of the lowest row of values (1893 group) does not materially alter the result.)

These latter values we find rising (with one slight break) to a maximum in the *second* year after the sunspot maximum, then sinking rapidly to a minimum in the fifth year, and continuing under average in the two following years.

It will be noted that in the enclosed groups *a* to *b*, the + signs largely preponderate (16 + to 7 −); that they preponderate in each horizontal group, and in each vertical group but one; and that the sums of all those groups have + signs.

A. B. M.

The Epistemology of Natural Science and Mr. Karl Pearson.

ONLY a few days ago I happened to see the review of my "Erkenntnistheoretische Grundzüge der Naturwissenschaften" (Leipzig, 1896) in NATURE of November 5, 1896. I too highly esteem English science and literature to follow Mr. Karl Pearson in the department of his "familiar ideas"; I shall confine myself to showing how little my reviewer has succeeded in rendering my views (see p. 3).

I have nowhere called the undulatory *theory* of light an hypothesis; I have called the undulatory *conception* (Vorstellung) of light an hypothesis. I have nowhere said that "it is the *sinnliche Wahrnehmung* which changes the *Hypothese* to the *Naturgesetz*." Perception, as was seen in the case of photographs of light-waves obtained by Prof. Wiener, makes hypothesis a matter of fact. To call this fact a law, has never come into my mind.

I have nowhere stated Galilei's law of inertia to be a law of nature; I have declared it to be a postulate laid down on the basis of rich empirical materials (ein auf grundreichen empirischen Materials aufgestelltes Postulat, p. 169). Newton's law of gravitation and the principle of energy are typical examples of natural laws. The law of inertia belongs to the "axiomata sive leges motus" of Newton, and in this respect I have compared the law of inertia to the axioms of geometry, and, considering the rich experience of *to-day*, I have spoken as of an *appearance* of obviousness and immediateness (von einem *Scheine* des Einleuchtenden und Unmittelbaren, p. 168). How little I really think the law of inertia to be so obvious and immediate (so einleuchtend und so unmittelbar), my reviewer might also have learned from pages 74–76 of my book. In a postulate, as well as in a law of nature, immediate perception is entirely out of the question.

These few examples will suffice to show that my reviewer, perhaps owing to some difficulties in understanding the German language, has constructed certain ideas which, in fact, do not exist at all, and are, by no means, advocated by myself. As it is, I do not feel obliged to enter into a discussion of his other remarks, in which he, at least, quotes from my book correctly.

PAUL VOLKMANN.

University of Königsberg, January 18.

FOR our *Principle of Inertia* the Germans use two expressions, *Trägheitsprincip* and *Trägheitsgesetz*. Dr. Volkmann in his work almost invariably adopts the latter, and even speaks of the principle of inertia as *das physikalische Gesetz der Trägheit*. If a physical law be not a law of nature, Dr. Volkmann ought to have carefully distinguished between a *Naturgesetz* and a *physikalisches Gesetz*. I am sorry, however, to have given him more credit for logical consistency than he desires to lay claim to. The law of inertia describes how an insensible particle would move relatively to certain "fixed axes" under certain purely conceptual, not physically realisable conditions. The law of gravitation describes how two insensible particles would move relatively to certain "fixed axes" under certain purely conceptual, not physically realisable conditions. If Dr. Volkmann wishes to draw a distinction between the two, and calls the latter alone a law of nature, then my opinion of his *Erkenntnistheoretische Grundzüge* is now lower than it was when I wrote my notice of it. Dr. Volkmann refers me to pp. 74–76 of his work to illustrate that he did not consider the law of inertia *so einleuchtend und so unmittelbar*, yet those are precisely the pages from which I cited in my review the motion of the railway train, which Dr. Volkmann considers can illustrate the law of inertia, an example which I hold to be most illusory. It is especially dangerous to the young student, and most misleading in popular lectures like Dr. Volkmann's *Allgemein wissenschaftliche Vorträge*.

Dr. Volkmann tells us that Wiener's researches have changed the undulatory conception (*Vorstellung*) of light into *eine vollendete Thatsache*, it has now ceased to be an hypothesis. How a conception can become a physical fact by any amount of research, I fail to understand; although I do grasp how the contents of that conception may by new discoveries be found to adequately describe our physical sensations. But when the contents of the conception are found to adequately describe our sensations, then it seems to me that the orderly account of those contents, which we term theory, ceases to be hypothesis, and becomes a law of nature. If Wiener's work makes the undulatory conception an adequate account of sensation, then it converts the undulatory theory into a law of nature. But Dr. Volkmann tells us this is not what he has said. Perhaps the undulatory theory, now that the undulatory conception has become *eine vollendete Thatsache*, still remains a theory, or is a postulate, or a physical law, or something else in Dr. Volkmann's classification. I certainly do not sufficiently grasp Dr. Volkmann's *Grundzüge* to be able to classify it.

Lastly, I hope my "understanding of the German language" has misled me; otherwise I should say that Dr. Volkmann's present interpretation of what he has written on p. 168 "appears" to me disingenuous. What he has written there runs:—

"Wir befinden uns dem Trägheitsgesetz gegenüber heute vielleicht in ähnlicher Lage wie der Geometer seinen Axiomen gegenüber, dem es gerade darum so schwer fällt, an seinen elementaren Sätzen erkenntnistheoretische Studien anzustellen, weil der Inhalt dieser Sätze so einleuchtend, so unmittelbar zugänglich ist. So scheint dem Physiker heute das Trägheitsgesetz so einleuchtend, so unmittelbar, dass es als Axiom vorgetragen zu werden pflegt. Aber es gab eine Zeit, wo der Inhalt des Trägheitsgesetzes dem menschlichen Geiste durchaus nicht so unmittelbar zugänglich erschien, und dies werden wir uns zu vergegenwärtigen haben, um die Bedeutung der Galileischen Forschung noch heute würdigen zu können."

I take this to mean that the law of inertia appears obvious to the physicist of to-day, but at the time of its discovery it was not at all an obvious conception. Dr. Volkmann says that in this passage he has spoken *von einem Scheine des Einleuchtenden und Unmittelbaren*. He has certainly used the verb *scheinen*, but when I say, for example, that twice two makes four *appears* to me a direct and obvious truth, I certainly do not mean to indicate that the directness and obviousness are *specious*. I must apologise to Dr. Volkmann for having misunderstood this subtlety of the German language.

It is perhaps necessary to add that Dr. Volkmann is raising a verbal controversy which has nothing to do with our radical difference of view. For me a law of nature is purely a product of the human intellect; it is a formula which describes in the briefest terms yet discovered as wide a range as possible of the motions we attribute to atoms, particles, molecules, ether, &c., which kinetic *concepts* form parts of the entirely *conceptual* model by aid of which we describe the sequences of our physical sensations. For Dr. Volkmann the law of nature is something existing *ausser uns* (p. 56) in some manner kept in harmony with the *Denknothwendigkeiten in uns*. Presumably the law lies in the *Dinge an sich*, for it would be impossible to find a law like that of gravitation in the contents of our physical sensations. It is at this point that the older view of the physical sciences, as something quite different from *descriptive* sciences, runs us aground on the metaphysical mudbank. KARL PEARSON.

Durham Degrees in Science.

JUST two remarks in answer to the Rev. Henry Palin Gurney's letter in your last issue.

He admits by his silence my main contention, viz.—that the nature of the M.Sc. degree at Durham has been radically changed owing to the recent action of the University in granting the degree by vote of Convocation.

I did not insinuate in my letter that "these gentlemen had no qualification for the honour."

It is impossible for me to know the necessary qualifications for the degree other than those published by the University in their Calendar. It was sufficient for me that the latter were ignored. X.

February 6.

ON THE CONDUCTIVE EFFECT PRODUCED IN AIR BY RÖNTGEN RAYS AND BY ULTRA-VIOLET LIGHT.[1]

WE propose in this communication to describe results of experiments on the electrical effects of Röntgen rays and of ultra-violet light when shone on metals, or through air between two metals mutually insulated; and electrified to begin with, by previously producing a difference of potentials between platinum electrodes of an electrometer metallically connected with them. In some of our experiments this potential-difference was zero, and the initial ± electrifications of the opposed surfaces depended solely on difference of volta-electric quality between their opposed surfaces.

To investigate the effects of Röntgen rays, a hollow cylinder of unpolished aluminium connected to the

[1] A paper by Lord Kelvin, Dr. J. C. Beattie, and Dr. Smoluchowski de Smolan, read before the Royal Society of Edinburgh, February 1.

electrometer sheaths was used. Along the axis of this a metallic bar was placed, supported by its ends on small blocks of paraffin so situated as not to be shone on by the Röntgen rays. This insulated metal was connected by a copper wire to the insulated terminal of the electrometer. To protect it from inductive effects it was enclosed in a lead tube connected to the other terminal and to sheaths (see Diagram 1).

The Röntgen lamp was placed in a lead cylinder connected to sheaths. The rays passed into the tube of aluminium through a window in the lead cylinder, which could be screened or unscreened at will, as described in our former paper (*Proc. R.S.E.*, December 1896).

The course of the experiment was the same with each insulated metal. The metal was charged first positively, then negatively; the Röntgen rays were then shone on it through the aluminium cylinder surrounding it, and the electrometer readings taken at fixed intervals, until a steady reading on the electrometer was obtained. The point at which the electrometer reading remained steady with the rays acting we shall call the *rays-zero*.

Finally, the insulated metal was discharged by metallic connection in the electrometer, and re-insulated; the

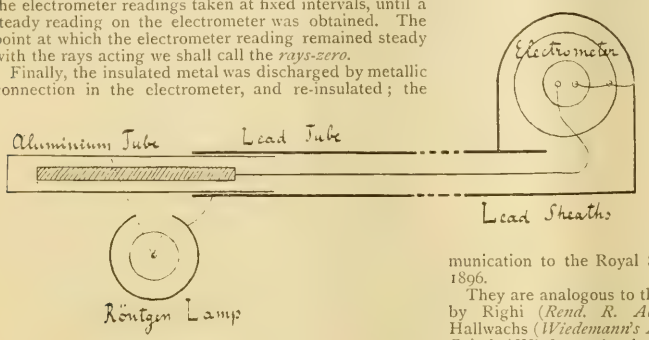


DIAGRAM 1.

rays were again shone on it until the rays-zero was again reached.

The following figures, taken from the laboratory book, show the effect obtained in this way when the insulated metal was amalgamated zinc.

The zero with the electrometer quadrants in metallic connection we shall afterwards speak of as the *metallic zero*.

December 31, 1896, 5.56 p.m.—Readings with one pair of electrometer quadrants insulated, and with Röntgen lamp acting.

− 72	scale divisions from metallic zero after				5 secs.
− 87	,,	,,	,,	,,	10 ,,
− 91	,,	,,	,,	,,	15 ,,
− 92	,,	,,	,,	,,	30 ,,
− 93	,,	,,	,,	,,	2 mins.

Afterwards steady.

Thus the difference between the rays-zero and the metallic zero is in this case − 93 scale divisions, or − 0·66 of a volt.

[Sensibility of electrometer 140 divs. per volt.]

This deviation from the metallic zero was not stopped by placing an aluminium screen over the window of the lead cylinder; on the other hand, it was stopped if a lead screen was used. If a positive or a negative charge was given to the insulated metal and the Röntgen rays were shone through the aluminium cylinder surrounding it, the discharge went on till the rays-zero was reached; only then was the electrometer reading steady.

In the following table, Column II. gives the potential differences of the rays-zero from the metallic zero for twelve different metals insulated within the unpolished aluminium cylinder as described above. Column III. gives the differences for two of the same metals in the interior, but with the surrounding aluminium cylinder altered by its inner surface being polished by emery paper.

I. Insulated metal.	II.	III.
Magnesium tape	− 0·671 of a volt	
Amalgamated zinc ...	− 0·66 ,, ,,	
Polished aluminium ...	− 0·465 ,, ,,	
Polished zinc	− 0·343 ,, ,,	
Unpolished aluminium	− 0·349 ,, ,,	... + 0·35 of a volt
Polished lead	− 0·257 ,, ,,	
Polished copper	+ 0·129 ,, ,,	
Polished iron nail	+ 0·182 ,, ,,	
Palladium wire	+ 0·255 ,, ,,	
Gold wire	+ 0·264 ,, ,,	... + 0·930 of a volt
Carbon	+ 0·429 ,, ,,	

It is to be noted that the preceding experiments tell us insufficiently as to what would happen had we shone the rays on an insulated metal surrounded by an absolutely identical metallic surface connected to sheaths. Another experiment towards answering this question will be described in a later part of our paper.

The preceding results of the action of Röntgen rays are very similar to, and wholly in accordance with, the results found by Mr. Erskine Murray, and described by him in a communication to the Royal Society of London, March 19, 1896.

They are analogous to those found for ultra-violet light by Righi (*Rend. R. Acc. dei Lincei*, 1888, 1889); Hallwachs (*Wiedemann's Annalen*, 34, 1888); Elster and Geitel (*Wiedemann's Annalen*, 38, 41, 1888); Branly (*Comptes rendus*, 1888, 1890), and others.

We have also made some experiments with ultra-violet light, in which this similarity is further brought out. The method we have employed is that of Righi.

A cage of brass wire gauze was made and connected to sheaths. Inside it the insulated metal was placed on a block of paraffin, and connected to the insulated terminal of the electrometer by a thin copper wire protected

DIAGRAM 2.

against inductive effects. The light from an arc lamp was then shone through the gauze so as to fall on the insulated metal perpendicular to its surfaces (see Diagram 2).

The experiments were of the same nature as those with the Röntgen rays, except that wire gauze letting through the ultra-violet light was substituted for the non-perforated aluminium cylinder transparent to the Röntgen rays. The insulated metal disc was 2 cms. distant from the gauze of brass wire. The steady electrometer readings after the two pairs of quadrants were insulated and the ultra-violet light shining (which we shall hereafter refer to as the *ultra-violet-light-zero*) was observed.

The insulated metal was afterwards charged positively, and then negatively. The rate of discharge was observed till the ultra-violet-light-zero was reached.

With polished zinc as the insulated metal the following results were obtained.

The insulation was first tested. When no ultra-violet light was used it was found that the electrometer reading remained the same whether the two pairs of quadrants were in metallic connection or not. With the ultra-violet light shining the reading with the quadrants in metallic connection was the same as before, the readings with the quadrants disconnected were :—

January 14th, 3h. 41m. p.m.

− 25	sc. divs.	from metallic zero	after	15 secs.
− 45	,,	,,	,,	30 ,,
− 59	,,	,,	,,	45 ,,
− 67	,,	,,	,,	1 min.

− 124	,,	,,	,,	1 min.
− 113	,,	,,	,,	2 ,,
− 111	,,	,,	,,	3 ,,

Afterwards steady.

The following table shows the steady potential differences in the electrometer due to the conductive effect of ultra-violet light in our apparatus between the brass wire gauze and plates of various other metals.

Insulated metal :—

Polished zinc	− 0·75 of a volt.
Polished aluminium ...	− 0·66 ,,
German silver	− 0 19 ,,
Gilded brass	+ 0·04 ,,
Polished copper ...	+ 0·12 ,,
Oxidised copper ...	+ 1·02 ,,

The copper was oxidised by being held in a Bunsen flame.

In the case of polished zinc, polished aluminium, polished copper, and oxidised copper, both positive and negative charges were discharged at the same rate, if we reckon the charge of the insulated metal from its ultra-violet-light-zero. The rates of reaching the ultra-violet-light-zero were not observed for gilded brass and German silver.

It must again be noticed that our experiments do not tell us what would happen if an insulated metal, shone on by ultra-violet light, were surrounded by a metal of precisely the same quality of surface connected to sheaths.

So far we have mentioned only experiments in which the rays, whether Röntgen or ultra-violet, fell perpendicularly on the insulated metal. We have also made some experiments with the rays going parallel to the metal surfaces.

For this purpose a cardboard box 46 cms. long, 19 cms. square (see Diagram 3), lined, in the first instance, with tinfoil, connected to sheaths, was used. Inside this box an insulated disc of oxidised copper of 10 cms. diameter was supported in such a way as to allow of its being fixed at different distances from the tinfoil-coated end-wall of the box facing it.

The distance between the disc and the tinfoil was at first 4 cms. The arc lamp was distant about 20 cms. from the box. The light from it shone through a slit in the tinfoil covering the side of the box perpendicular to the surface of the oxidised copper. The slit was 4 cms. long, 1 cm. broad. Its length was first placed parallel to the copper surface, so that the light admitted by it shone in the space between the two metals in such a way as not to illuminate either directly. It was found (1) that the ultra-violet-light-zero did not deviate from the metallic zero when the sheet of light passed between the two metals ; (2) that a negative charge given to the insulated oxidised copper was not discharged ; and (3) that a positive charge was removed very slowly—about four scale divisions per minute from a charge of 197 scale divisions from the metallic zero.

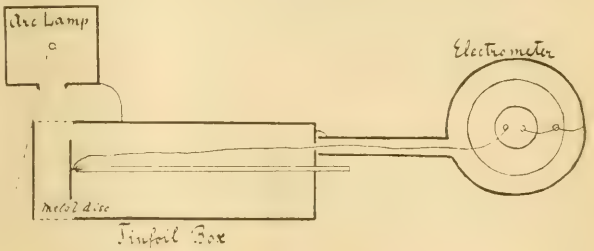

DIAGRAM 3.

When the length of the slit was placed perpendicular to the surface, so that a small portion of both metals, as well as the intervening air, was illuminated, it was found that the reading deviated about + 1 scale division per minute from the metallic zero. The oxidised copper was charged positively ; and negatively. Discharge took place at about four scale divisions per minute, from a charge of + 202 scale divisions ; and three scale divisions per minute from a charge of − 246 scale divisions : the charge reckoned from the metallic zero in each case.

The slit was then so arranged as to allow the light to shine on the oxidised copper alone. In this case the deflection went towards an ultra-violet-light-zero at about + 6 sc. divs. per minute ; and both positive and negative charges were discharged, the negative much more quickly than the positive.

The ultra-violet light was now shone between the oxidised copper and the disinsulated tinfoil wall opposite to it, parallel to their surfaces so as to illuminate both. The difference between the metallic zero and the ultra-violet-light-zero was found to depend on the distance between the two surfaces. This will be seen from the following table :—

Jan. 28.	Ultra-violet-light-zero.		Distance between surfaces.	Time required to come to steady reading.
12.20 p.m.	+150	sc. divs. from metallic zero	4·3 cms.	4 mins.
2.0 ,,	+134	,, ,,	3·0 ,,	9 ,,
2.10 ,,	+121	,, ,,	2·0 ,,	5 ,,
2.20 ,,	+102	,, ,,	1·0 ,,	5 ,,
2.40 ,,	+ 86	,, ,,	0·6 ,,	5 ,,
2.50 ,,	+169	,, ,,	4·0 ,,	10 ,,
3.0 ,,	+161	,, ,,	5·0 ,,	5 ,,
3.20 ,,	+199	,, ,,	7·0 ,,	5 ,,

[Sensibility of electrometer 140 sc. divs. per volt.]

The fact that in experiments (2) and (6) a longer time was required before a steady reading was obtained, probably depended on the way the light fell on the surfaces and on variations in intensity of the light.

In this table we see that the steady electrometer reading (which we have called the ultra-violet-light-zero) is largely influenced by the distance between the plates, being greater the greater the distance. This is a very remarkable result. It was first discovered by Righi, and very clearly described in papers of his to which we have referred. It may be contrasted with the non-difference of electrometer readings for different distances between the plates in a volta-zinc-copper and single fluid cell.

Added February 6. [We have also made an exactly similar series of experiments with Röntgen rays. The same insulated oxidised copper plate was placed inside the same tinfoil box, and the Röntgen rays shone in between the two metals so as to shine on both. The following results were obtained with the oxidised copper at different distances.

February 5, 11.30 a.m.

Rays-zero.	Distance between surfaces.
+23·5 sc. divs. from metallic zero ...	1·2 cms.
+25·0 ,, ,, ,, ...	2·2 ,,
+23·0 ,, ,, ,, ...	3·8 ,,
+23·0 ,, ,, ,, ...	6·0 ,,

We next removed the oxidised copper plate, and substituted a polished zinc disc. With it we obtained the following results.

Rays-zero.	Distance between surfaces.
−82 sc. divs. from metallic zero ...	1 cm.
−79 ,, ,, ,, ...	1·5 ,,
−81 ,, ,, ,, ...	3·0 ,,
−90 ,, ,, ,, ...	7·0 ,,
−90 ,, ,, ,, ...	7·5 ,,

The steady reading of the rays-zero was very nearly reached in each case in about 15 secs., but the observation was continued for one or two minutes till we found the reading steady.

Thus we see that, as previously found by Mr. Erskine Murray, the rays-zero is independent, or nearly independent, of the distance between the opposed metallic surfaces.]

Towards realising the case of an insulated metal surrounded by metal of identical surface-quality connected to sheaths, we covered over the oxidised copper with tinfoil. The tinfoil wall facing it was very rough, and not so well polished. The insulated tinfoil was 4 cms. distant from the end of the box to which its surface was parallel.

When the ultra-violet light fell on the insulated metal alone through a slit, the ultra-violet-light-zero was + 53 scale divisions from the metallic zero. A charge given to it, whether positive or negative, was discharged slowly. After making these experiments, we again observed the difference of zeros, and found that now the ultra-violet-light reading was at the end of the first four minutes + 2 scale divisions from the metallic zero; at the end of the next four minutes it was − 8 scale divisions from it.

When the ultra-violet light fell on the disinsulated metal and not on the insulated, the insulated when charged retained its charge.

With the light shining on both through a window 7 cms. broad, 13 cms. high, both positive and negative charges given to the insulated metal were discharged, and the ultra-violet-light-zero deviated from the metallic zero by − 152 scale divisions.

This difference was reduced to about − 30 scale divisions when the experiments were repeated after the apparatus had been left to itself for a night.

To make similar experiments with the Röntgen rays, it was found necessary to cover the window near the lamp with tinfoil gauze connected to sheaths, and the window on the opposite side was covered with non-perforated tinfoil. In this way direct electrostatic induction was avoided. We had also a thin sheet aluminium window between the tinfoil gauze and the Röntgen lamp.

When the Röntgen rays fell on both insulated and disinsulated metal the rays-zero was − 5 scale divisions from the metallic zero, and both positive and negative charges fell to this zero in a few seconds.

With the rays shining only on the insulated metal the same small difference of zeros was obtained, and both positive and negative charges fell to the rays-zero, though much more slowly than before—in about four minutes.

With the Röntgen rays shining on the insulated tinfoil through the disinsulated tinfoil gauze, the rays-zero was − 9 scale divisions from the metallic zero, and both positive and negative charges were removed in about a minute.

On substituting an aluminium gauze for the tinfoil gauze, and sending rays through it on the insulated tinfoil, the rays-zero was + 25 scale divisions from the metallic zero.

Added February 6. With a polished zinc disc as the insulated metal, and with the same windows to the tinfoil box, the Röntgen rays were shed in between the insulated zinc and the opposite wall of tinfoil from a slit in a lead screen outside. This slit was 4 cms. long by 1 cm. broad. The distance between the two metals was 7 cms. The rays illuminated only part of the air space between the two, and also a part of the tinfoil covering the two windows.

The following are some of the results obtained :—

[Sensibility of electrometer 140 sc. divs. per volt.]

February 5, 1897. Zinc charged negatively to 285 scale divisions from the metallic zero.

Reading from metallic zero with Röntgen lamp acting :—

	Time.
− 276 scale divisions ...	after 1 min.
− 265 ,, ...	,, 2 ,,
− 255 ,, ...	,, 3 ,,
− 243 ,, ...	,, 4 ,,
− 227 ,, ...	,, 5 ,,
− 214 ,, ...	,, 6 ,,
− 184 ,, ...	,, 8 ,,

Discharge still continued.

The zinc was then discharged by metallic connection. The readings, with the Röntgen light shining, and the two pairs of electrometer quadrants again disconnected, were :—

− 4 sc. divs. from metallic zero after	½ min.
− 13 ,, ,, ,,	1½ ,,
− 41 ,, ,, ,,	2½ ,,
− 53·5 ,, ,, ,,	3½ ,,
− 61 ,, ,, ,,	4½ ,,
− 67 ,, ,, ,,	5½ ,,
− 70·5 ,, ,, ,,	6½ ,,
− 71·0 ,, ,, ,,	7 ,,

The difference between the rays-zero and the metallic zero is thus found to be −71 sc. divs., or −0·5 of a volt. Immediately after this experiment, we removed the lead window and allowed the Röntgen light to shine on both

metals, still 7 cms. apart. We then found the difference of zeros to be − 89 sc. divs., or − 0·64 of a volt; but instead of seven minutes, scarcely a quarter of a minute was taken to reach the rays-zero after the metallic connection was broken. These results are substantially in accordance with Erskine Murray's §§ 9 of his paper already referred to.

KELVIN.
J. C. BEATTIE.
SMOLUCHOWSKI DE SMOLAN.

THE EFFECT OF MAGNETISATION ON THE NATURE OF LIGHT EMITTED BY A SUBSTANCE.[1]

IN consequence of my measurements of Kerr's magneto-optical phenomena, the thought occurred to me whether the period of the light emitted by a flame might be altered when the flame was acted upon by magnetic force. It has turned out that such an action really occurs. I introduced into an oxyhydrogen flame, placed between the poles of a Ruhmkorff's electromagnet, a filament of asbestos soaked in common salt. The light of the flame was examined with a Rowland's grating. Whenever the circuit was closed both D lines were seen to widen.

Since one might attribute the widening to the known effects of the magnetic field upon the flame, which would cause an alteration in the density and temperature of the sodium vapour, I had resort to a method of experimentation which is much more free from objection.

Sodium was strongly heated in a tube of biscuit porcelain, such as Pringsheim used in his interesting investigations upon the radiations of gases. The tube was closed at both ends by plane parallel glass plates, whose effective area was 1 cm. The tube was placed horizontally between the poles, at right angles to the lines of force. The light of an arc lamp was sent through. The absorption spectrum showed both D lines. The tube was continuously rotated round its axis to avoid temperature variations. Excitation of the magnet caused immediate widening of the lines. It thus appears very probable that the period of sodium light is altered in the magnetic field. It is remarkable that Faraday, as early as 1862, had made the first recorded experiment in this direction, with the incomplete resources of that period, but with a negative result (Maxwell, "Collected Works," vol. ii. p. 790).

It has been already stated what, in general, was the origin of my own research on the magnetisation of the lines in the spectrum. The possibility of an alteration of period was first suggested to me by the consideration of the accelerating and retarding forces between the atoms and Maxwell's molecular vortices; later came an example suggested by Lord Kelvin, of the combination of a quickly rotating system and a double pendulum. However, a true explanation appears to me to be afforded by the theory of electric phenomena propounded by Prof. Lorentz.

In this theory, it is considered that, in all bodies, there occur small molecular elements charged with electricity, and that all electrical processes are to be referred to the equilibrium or motion of these "ions." It seems to me that in the magnetic field the forces directly acting on the ions suffice for the explanation of the phenomena.

Prof. Lorentz, to whom I communicated my idea, was good enough to show me how the motion of the ions might be calculated, and further suggested that if my application of the theory be correct there would follow these further consequences: that the light from the edges of the widened lines should be circularly polarised when the direction of vision lay along the lines of force; further, that the magnitude of the effect would lead to the determination of the ratio of the electric charge the ion bears to its mass. We may designate the ratio e/m. I have since found by means of a quarter-wave length plate and an analyser, that the edges of the magnetically-widened lines are really circularly polarised when the line of sight coincides in direction with the lines of force. An altogether rough measurement gives 10^7 as the order of magnitude of the ratio e/m when e is expressed in electromagnetic units.

On the contrary, if one looks at the flame in a direction at right angles to the lines of force, then the edges of the broadened sodium lines appear plane polarised, in accordance with theory. Thus there is here direct evidence of the existence of ions.

This investigation was conducted in the Physical Institute of Leyden University, and will shortly appear in the "Communications of the Leyden University."

I return my best thanks to Prof. K. Onnes for the interest he has shown in my work. P. ZEEMAN.

Amsterdam.

[1] Translated by Arthur Stanton from the *Proceedings* of the Physical Society of Berlin.

NOTES.

THE Council of the Royal Society have invited Prof. C. S. Sherrington, F.R.S., Professor of Physiology in University College, Liverpool, to deliver the Croonian Lecture on April 1, the subject being "The Spinal Cord and Reflex Actions."

TUESDAY'S *Gazette* contains the formal intimation that the dignity of a Baron of the United Kingdom has been granted to Sir Joseph Lister, Baronet, President of the Royal Society, by the title of Baron Lister, of Lyme Regis, in the county of Dorset.

PROF. DR. RUDOLF VIRCHOW has been elected president of the German Anthropological Society for the year 1897.

IT is expected that Prof. Barnard will attend the meeting of the Royal Astronomical Society to-morrow, February 12, to receive the gold medal which has been awarded him for his numerous contributions to astronomy. Sir Robert Ball has been nominated as the new president of the Society.

THE Council of the Royal Meteorological Society have arranged to hold, from March 16 to 19, in commemoration of the diamond jubilee of H.M. the Queen, an exhibition of meteorological instruments in use in 1837 and in 1897, and of diagrams, drawings, and photographs illustrative of the advances which have been made.

THE Government of the Colony of the Cape of Good Hope has undertaken an investigation of the marine fauna of the South African coast, with reference both to economic value and scientific interest. A small marine station will probably be erected on False Bay, and a suitable steam vessel of about 150 tons is now being built for this purpose. It is confidently hoped that results of some scientific value may be obtained from the exploration of this little-known coast, and more especially of the Agulhas Bank. We are requested to state that the services of specialists are invited to work up the material that may be procured, under the following arrangements. Specimens will be forwarded as procured, and, on receipt of manuscript and drawings, each piece of work will be published without delay in a uniform style, so as to form ultimately a complete record of the Cape marine fauna. Authors' copies will be forwarded as soon as published, and a certain circulation will be guaranteed. No money remuneration is offered, but duplicate specimens may be retained by the authors. Unique specimens it is intended to be handed over to the South African Museum in Cape Town. Further information will be supplied to those interested in the work, on application to J. D. F. Gilchrist, Marine Biologist to the Cape Government Agricultural Department, Cape Town.

ON Wednesday evening, February 3, the Leathersellers' Company entertained at a Court dinner a considerable number of representatives of the colonies and dependencies of the empire, including Sir Donald Smith (High Commissioner for Canada), Sir Saul Samuel (Agent-General for New South Wales), and many others. The company also included many of the scientific friends of the Master, Dr. W. H. Perkin, F.R.S., himself one of the foremost of British chemists, and popularly known as the discoverer of "mauve," the first of the colours derived from coal-tar. The Leathersellers' Company, like others of the great guilds of London, are now devoting part of their revenues to promoting scientific education with a view especially to its application to industrial pursuits; and, recognising the importance not only of elementary instruction, but the cultivation of the highest branches of scientific work, they have recently established a research scholarship, of the value of £150 a year, in connection with the Central Technical College of the City and Guilds of London Institute (see p. 332).

THE late M. James Lloyd, of Nantes, author of the "Flore de l'Ouest de la France," who died in May last, has bequeathed his fortune and his collections to the town of Angers. The latter consist chiefly of a herbarium and a botanical library, which are to be housed in a special building, and funds are left for their maintenance, and for the payment of a curator, who is to be selected by the Mayor of Angers from a list of three candidates to be nominated by the President of the Botanical Society of France. The names of candidates are to be sent to the President of the Society, 84 Rue de Grenelle, Paris, by March 15, and the post is to be conferred "en dehors de toute considération de grades universitaires," on "un botaniste humble, ami de la nature, voué au progrès de la science que j'ai aimée et cultivée.".

THE Vienna Academy of Sciences has (says the *Lancet*) employed a portion of the Treitl Fund in sending a commission, composed of Dr. Hermann Müller, Dr. Ghon, Dr. Albrecht, and Dr. Pöch, to investigate the nature of the bubonic disease now prevailing in India. The members of the expedition have just left Trieste, and will remain at Bombay for three or four months. The Treitl Fund is so called after the late Herr Treitl, a Vienna citizen, who bequeathed to the Academy all his fortune, amounting to about £100,000.

IN view of the increasing interest now being taken in the subject of aerial navigation, it has been decided to endeavour to place the Aeronautical Society on a more useful footing. The Council propose, should sufficient support be given, to greatly increase the scope of the Society; to issue a journal at least quarterly, containing not only reports of meetings of the Society, but original articles, reprints, and records of all that is going on at home and abroad in the subject of aeronautics, and all news likely to be of interest to members; to hold frequent meetings for the reading and discussion of papers and exhibition of models; to collect a library of books and periodicals for reference of members; and, if possible, to procure the use of a room as library and museum. The Hon. Secretary of the Society is Captain B. Baden-Powell.

WE regret to announce the deaths of the following men of science:—Heinrich Gätke, the ornithologist, whose observations on bird-migration for fifty years are published in his "Heligoland as an Ornithological Observatory"; Prof. Franz Baur, professor of forestry in Munich University; Dr. August Streng, professor of mineralogy in the University of Giessen; Dr. E. A. B. Lundgren, professor of geology in the University of Lund; A. A. van Bemmelen, director of the Zoological Gardens at Rotterdam, and for many years president of the Netherlands Zoological Society; Dr. Hermann v. Nördlinger, formerly professor of forestry in the University of Tübingen; Dr. Salvatore Trinchese, professor of comparative anatomy and comparative embryology in the University of Naples, and the author of many valuable works in general biology; and Galileo Ferraris, the well-known electrician, of Turin.

FIFTY years spent in scientific investigation is a period worth commemorating. We therefore offer our congratulations to Dr. H. C. Sorby, F.R.S., upon the attainment of his jubilee as contributor to the advancement of natural knowledge. From the *Sheffield Daily Telegraph* we learn that a few evenings ago Dr. Sorby inaugurated his year of office, as President of the Sheffield Literary and Philosophical Society, by giving an address upon a half-a-century spent in scientific work. In this interval he has published more than one hundred papers, which have made for the progress of science. His first papers were on animal and vegetable chemistry; the earliest being published in 1847. Very soon afterwards his attention was specially directed to the structures produced by currents during the deposition of stratified rocks, and to the conclusions to be derived from them. In 1849 he prepared what were the first transparent microscopical sections of rocks, and his first paper on thin microscopical structures was published in 1850, in which most of the modern methods were first adopted. That was followed by numerous papers on the structure of rocks and minerals, or on chemical or physical questions connected with them. From the study of the microscopical structure of rocks, he was led to that of meteorites and meteoric iron. In order to throw light on that subject he commenced, in 1842, the microscopical study of iron and steel by new methods and new illuminators. In order to assist in the study of meteorites, Dr. Sorby invented, in 1865, the direct-vision spectrum microscope, and various accessory apparatus. The application of those instruments led to the study of the colouring matters of animals, plants and minerals, and to the publication of about forty papers connected with almost every department of science. Dr. Sorby has also advanced many other branches of knowledge, his researches on marine organisms, and in connection with the archæology of natural history, being especially noteworthy. Nearly thirty years back the value of his work was recognised by the presentation of the Wollaston gold medal from the Geological Society. A quarter of a century ago the Dutch Academy of Sciences made him the first recipient of the Boerhaave gold medal, which is only awarded once in twenty years. Two years afterwards—in 1874—the Royal Society awarded him a Royal medal. Then followed the honorary degree of LL.D., conferred upon him by Oxford University. Dr. Sorby's services to science have thus been recognised by various authorities, and we trust he may still live long to add to the researches which have enriched the storehouse of knowledge.

THE annual general meeting of the Society for the Protection of Birds will be held on Tuesday, February 23, at the Westminster Palace Hotel. The Earl of Stamford will occupy the chair.

THE *Weekly Weather Report*, issued by the Meteorological Office, states that for the week ending the 6th inst. the rainfall was much in excess of the mean over England and the south of Ireland, the fall being in most cases three and four times as great as the average value. Over Scotland and the north of Ireland the amount was less than normal. In most parts of England the rainfall since the beginning of the year is about an inch above the average, while in the north and west of Scotland the deficiency is about four inches.

THE *Rendiconti del Reale Istituto Lombardo* announces the award of the following prizes:—One of the five Cagnola prizes of 2500 lire, and a gold medal, of value 500 lire, to Dr. Andrea

Giulio Rossi, of Padua, for his essay on methods of registering the phases of two alternating currents. The Brambilla prize of 1500 lire and a gold medal are awarded to Prof. Carlo Figini, for his improvements in the weaving industry; and rewards, of 500 lire each, to Signor Sala Salvatore and Signor Scartazzi Antonio. The Fossati prize of 2000 lire is awarded to Prof. Angelo Mosso, of Turin, for his essay on the temperature of the brain. For the Tommasoni prize for an account of the life of Leonardo da Vinci, rewards of 1000 lire each have been awarded to Signor Nino Smiraglia Scognamiglio and Prof. G. B. De Toni. A number of other prizes have been unawarded.

FOR the coming year, the Reale Istituto Lombardo offers the following prizes, which are open to competitors of all nationalities, on condition that the essays are written in Italian, French, or Latin. The prize of the Institution of 1200 lire, for experiments confirming Maxwell's theory of dielectric stresses; six Cagnola prizes of 2500 lire, each accompanied by a gold medal of 500 lire, for essays on various selected subjects, mostly medical; one Brambilla prize, for improvements in some industry in Lombardy; one Secco-Comneno prize of 864 lire, for an essay on uræmia; and prizes founded by the brothers Giacomo and Filippo Ciani, for popular Italian literary works. A number of other prizes are also announced in the *Rendiconti* of the Institution, both for competition in 1897 and later years; but many of these are exclusively open to Italians. A full account of the conditions attaching to the various competitions is given in the journal in question.

AT the ninth annual meeting of the American Physiological Society, held in Boston and Cambridge, December 29 and 30, 1896, Prof. W. H. Howell proposed the following resolution regarding the work of the late Prof. H. Newell Martin:—"The members of the American Physiological Society have heard with profound regret of the death of Prof. H. Newell Martin. In commemoration of his distinguished services, the Society adopts and places upon its official record the following expression of its appreciation and esteem. In the death of Prof. Martin, the Society has lost a member to whom it owes an especial debt of gratitude. He was actively concerned in its foundation and organisation, and during the critical period of its early history he gave much time and thought to its interests. He served for six years as its secretary and treasurer, and strove always with enthusiasm to make a successful beginning of an enterprise which he believed would foster the spirit of scientific research in physiology, and bring its active workers into stimulating fellowship. For its present prosperous condition, and its prospects of future usefulness, the Society feels that it is largely indebted to his wisdom and energy. In a broader field his influence upon the science of physiology has been deeply felt. His own splendid contributions to experimental physiology will have an enduring value, while the stimulus given by him to others has been, and will continue to be, an influential factor in the development of physiological instruction and research in this country. As an investigator and teacher he was distinguished, not only by his originality and ability, but by many noble traits of character. His modesty, his genuine interest in all kinds of biological work, his steady insistence upon the highest ideals of scientific inquiry, his chivalrous conception of the credit due to his fellow-workers, and the generous sympathy and affection always felt and shown by him for the work of younger investigators, are some of the qualities which will endear his memory to those who were so fortunate as to be brought into intimate association with him as teacher or as friend." Prof. H. P. Bowditch, in seconding the resolution, said:—"Probably few of the younger members of the Society are aware of the great debt which we owe to Dr. Martin for establishing the high standard which the Society has always maintained with regard to the qualifications of the members. It was always Dr. Martin's contention that a candidate for admission to our ranks should be required to demonstrate his power to enlarge the bounds of our chosen science, and not merely to display an interest in the subject and an ability to teach text-book physiology to medical students. To his wise counsel in this matter the present prosperity of the Society is, I think, largely to be attributed. I trust that the resolution will be adopted, and placed upon the records of the Society." The resolution was unanimously adopted.

THE manna sent to the Israelites on their journey out of Egypt to the Holy Land is regarded as identical with an edible lichen in Kerner and Oliver's "Natural History of Plants"; and the older view that it was the sap of a tamarisk, exuded under the influence of a parasite, is held to be without foundation. Mr. M. J. Teesdale reviews the subject in the February number of *Science Gossip*, and the evidence he brings forward is opposed to the conclusion to which reference has been made. He shows that an exudation from the twigs of the tamarisk (*Tamarix gallica*) has more points of resemblance with the manna of the Israelites than either the edible lichen or the sweet gums exuded by leguminous shrubs, such as *Alhagi maurorum* or *A. desertorum*—both known to the Arabs as camel's-thorn.

HERR K. RODER gives, in a dissertation presented for a Leipzig degree, the results of an investigation as to the polar limit of true forest-land, as distinguished from tundra. The boundary line reaches its highest latitude in the old world in the Taimyr peninsula (72½° N.), runs eastward to the Tschuktschee peninsula, and there bends rapidly to the southward. On the west coast of America it begins near the Arctic circle, and goes gradually northwards to the Mackenzie delta, where it attains its highest latitude in about 69° N. The most southerly point is in 57° N. lat., on the East Main River, and from thence the limit crosses Labrador, Greenland and Iceland, in a direction trending towards the North Cape.

WE have received the third of the *Arbeiten aus dem Geographischen Institut der Universität Bern*, edited by Prof. Brückner, consisting of an exhaustive discussion, by Dr. Hermann Walser, of the surface changes which have taken place in the canton of Zürich since the middle of the seventeenth century. Dr. Walser takes, as his starting point, the topographical map of J. C. Gyger, published in 1667, and traces the subsequent topographical history of the district by reference to an immense number of papers and maps to the present time. He finds that geological and human agencies have combined during the last 240 years to greatly diminish the number and size of lakes in the canton, that the amount of deforestation has been trifling, and that the area occupied by vineyards has steadily increased.

THE spell of warm weather in the United States, from July 28 to August last, is stated by Prof. H. A. Hazen, in the *Monthly Weather Review*, to have covered a larger area, and given abnormally high temperatures for a greater number of consecutive days than ever before recorded.

A SOLAR halo, with two mock-suns, and a rainbow overhead, was seen by Mr. J. W. Scholes, Huddersfield, at about 12.30 p.m. on January 29. The mock-suns and the rainbow only lasted a few minutes, but the white solar halo remained visible for nearly half an hour.

IT will be remembered that, some years ago, experiments on rain-making were carried on in Texas. In a short *brochure*, Dr. W. Hentschel suggests a plan of artificially producing rain, based on the well-known effects of statical electricity in promoting the formation of drops. The suggestion is to

reverse Franklin's historic kite experiment, and instead of drawing electricity from the clouds, to electrify a balloon by means of a conducting cable connected with a dynamo. In this way, the writer maintains, the rainfall can be increased, or, possibly, even decreased, at pleasure.

IN an article entitled "Fog Possibilities," Mr. A. McAdie, in *Harper's Monthly Magazine* for January, refers to the possibility of dispelling fog from crowded thoroughfares. The experiments of Aitken and others have shown the close relationship between fog, cloud, or haze, and the number of dust particles in the air. If we can remove the dust from the air, we remove the nuclei of condensation. Dr. Lodge has pointed out various methods by which this can be effected in laboratory experiments, the most successful of which is electrification. The author considers that by this means the fog can probably be dissipated and the air clarified. The supply of fog may be such that there would be little appreciable diminution, but as a rule the fog is localised and has well-marked limits.

AN important series of experiments on the absorption of ultra-violet light by crystals, has been conducted at Geneva by M. V. Agafonoff, of St. Petersburg (*Archives des Sciences physiques et naturelles*, iv. 2). Among the 100 different crystalline substances observed, only two were found to exhibit differences of absorption according to the direction of polarisation of the light; these were tourmaline and hemimellitic acid, which gave different absorption spectra for the ordinary and extraordinary rays of a doubly-refracting prism. Isolated absorption bands are rare, and were only found in the seven following substances: sulphate of magnesium, sulphate of ammonium and nickel, ammoniacal alum, nitrate of nickel, nitrate of potassium, dithionate of barium, and anthraquinone. The thickness of the section seems to have very little influence on the limit of wave-length at which absorption commences. The powerful absorption of organic, as compared with inorganic compounds, suggests that highly complex molecules are more absorbent of ultra-violet light than simple molecules; and, if this be the case, the property may afford a test of the relative complexity of different compounds.

FROM Mr. William Barlow we have received a reprint of his important communication to the *Mineralogical Magazine*, entitled "On Homogeneous Structures and the Symmetrical Partitioning of them, with Application to Crystals." The author gives a new definition of homogeneous structure, and describes a method of realising, in a concrete form, the kind of repetition in space which constitutes homogeneity of structure. The total number of types, all of which can be represented in this way, is 230, this being the number of typical point systems described by Federow and Schönflies, derived by their extension of Sohncke's methods. These all fall into the thirty-two classes of crystalline symmetry. The author gives reasons for rejecting Fedorow's arguments in support of his recent attempt to select from among the types of homogeneous structure those which are possible for crystals, and he shows the possibility of so classifying all the conceivable ways of symmetrically partitioning all the types of homogeneous structure as to avoid all reference to the nature of the cell faces. Among the reasons for undertaking this classification, the chief one is the relation of symmetrical partitioning to certain stereo-chemical and other facts.

THE latest evidence as to the occurrence of Man in the Glacial Period has just appeared in the *American Geologist* (vol. xviii. p. 302), where Dr. E. W. Claypole records the finding of a grooved stone axe at a depth of 22 feet in the drift of North-central Ohio. The axe, which was partially imbedded in boulder clay, lay in a bed of coarse gravel 1 foot in thickness; above this was a bed of silt, 13 feet in thickness, and very tough below; interbedded in this were streaks of sand; finally, there were superimposed 8 feet of clay. Dr. Claypole regards these beds as having been "the deposits of the torrents of water and the still pools which characterise the flow from the front of a glacier in a flat country"; he supports his statement by a description of the district, and he also enters into the *bonâ fides* of the discoverer of the implement. The axe was made of a hard, banded green slate, but it was oxidised throughout, owing to the sulphureous character of the water in the gravel; the concentric lines of colour (limonite stains), parallel to the contour of the implement, prove that the change has taken place since it was fashioned by its Neolithic maker, and the rotten state of the stone shows that it must have been imbedded in the gravel for a very long time. It is always a difficult matter to sift the evidence of such finds, but this one appears to be worthy of the critical examination of American geologists and archæôlogists.

FOSSIL bones of the Pleistocene age have been brought to the Academy of Sciences of Philadelphia from Port Kennedy, Montgomery County, Pa. The fossil deposit seems almost unlimited; and while it contains no complete skeletons, it is, in many respects, the richest ever discovered. Bones form fully one-third of the material in the giant fissure, but most of them are so crushed and distorted as to be of no value. About forty distinct varieties of animals have been found in the mass.

PRESIDENT DAVID S. JORDAN, of Leland Stanford Junior University, Commissioner to investigate the condition of the fur seal, recommends, in his report to the Secretary of the Treasury, that the open season for the killing of females be abolished, to keep the Pribilof herd intact. He estimates the number of seals killed last summer as 440.000. About 27,000 pups died of starvation, and pelagic sealing caused the death of about 30,000. Since pelagic sealing began, more than 600,000 fur seals have been taken in the North Pacific and in Bering Sea, taking into account only those whose skins were brought to market. Many more were shot or speared, and lost. The number reported means the death of 400,000 females, the starving of 300,000 pups, and the destruction of 400,000 pups unborn.

THE January number of the *Quarterly Journal of Microscopical Science* contains only two memoirs, both of which are more than usually suggestive and interesting. Miss Lily Huie describes the results of a very precise and systematic investigation of the changes which take place in the protoplasm and nucleus of the gland-cells in the tentacles of the sun-dew *Drosera rotundifolia*, after the feeding of the leaf with pieces of white of egg. The first effect of the contact of the food appears to be the discharge of secretion from the gland cells. The secretion is formed at the expense of the basophile cytoplasm, which is stained by alkaline stains. The nucleus produces new cytoplasm of the same kind, by absorbing nutriment, converting it, and then "excreting" it. In this process the nuclear chromation takes the form of V-shaped chromosomes, and the nucleolus grows smaller and almost disappears. The nuclear chromation increases in bulk. Thus the changes which occur resemble those to which so much attention has been directed in mitosis or the division of the cell, and the conclusion is drawn that these changes indicate great activity in the nuclear organs, and are not exclusively characteristic of cell-division.

THE second paper in the January *Q. J. M. S.* is by Messrs. J. T. Wilson and J. P. Hill, of the University of Sydney, New South Wales, on the development and succession of the teeth in the marsupial *Perameles*, and in other marsupials. It is well known that only one tooth, the last of the premolars, is observed to be shed and replaced by a successor in

these mammals; and the view once generally accepted was that the other teeth corresponded not to the milk-teeth, but to the permanent teeth of higher mammals. The absence of milk-teeth, with the one exception, in marsupials has been regarded as indicating, not that they have disappeared in the evolution of these animals, but that they first arose in the later evolution of the higher mammals. Other views, however, have been maintained, namely, on the one hand, that the temporary dentition has been lost by the marsupials: and, on the other hand, that the existing anterior teeth are in reality milk-teeth whose successors have ceased to appear. Certain traces of teeth in the jaws of the embryo, precursors of the permanent teeth, have been explained as "prelacteal teeth" by those who advocate the latter view. In this memoir the authors claim to have proved that there is a complete series of these prelacteal teeth or their papillæ, and that they in reality represent the series of milk-teeth in the higher mammals. Thus the peculiarity of the marsupial dentition is that the temporary or milk teeth have become, with the exception of the last premolar, rudimentary, and the permanent teeth are completely developed before the young animal is weaned.

THE Johns Hopkins University Press, Baltimore, publishes a somewhat bulky "History of the Tobacco Industry in Virginia from 1860-1894," by Dr. B. W. Arnold.

DR. V. FATIO has sent us a copy of his guide to the hunting and fishing collection in the Swiss National Exposition of 1896. The volume contains some interesting information on the fishes of Switzerland.

BY the not very happy term "phenological," recent botanical writers speak of phenomena connected with the flowering of plants and other seasonal characters. The American botanist, Prof. L. H. Bailey, sends us a useful paper of "Instructions for taking Phenological Observations."

IN the concluding part of Dr. Bokorny's paper in the *Biologisches Centralblatt*, on the nutrition of green plants, he sums up in favour of the view that the first product of assimilation in green plants is formic aldehyde, from which are afterwards formed either albuminoids by the action of ammonia, or carbohydrates by condensation. Green fresh-water organisms play a very important part in the purification of running water by the oxidation of organic substances in suspension.

THE first number of vol. iv. of the *Bulletin* of the Laboratories of Natural History of the State University of Iowa contains papers about equally distributed between zoology and phytology:—On Plymouth hydroids, by C. C. Nutting; on the mollusks and brachiopods of the Bahama Expedition, by W. H. Dall; on the hymenoptera of the Bahama Expedition, by W. H. Ashmead; on the puff-balls of Eastern Iowa, by T. H. Macbride and Norra Allen; on new species of tropical fungi, by J. B. Ellis and P. M. Everhart; and others.

PROVINCIAL museums are following the lead of the National History Museum in issuing interesting and instructive handbooks on their collections, instead of mere catalogues of specimens. An admirable handbook of this character, referring to the mineralogical and geological sections of the Royal Museum of the County Borough of Salford, has been prepared by Mr. Herbert Bolton, who also re-arranged and named the collections. His little guide will arouse the interest of casual visitors, and will also greatly aid and encourage the study of geology.

A GENERAL meeting of the members of the Federated Institution of Mining Engineers will be held on Wednesday, February 17, at Manchester. The following papers will be read, or taken as read:—Railway nationalisation in relation to the coal trade, by Mr. A. Clement Edwards; the cost and efficiency of safety explosives as compared with gunpowder, by Mr. Henry Hall; description of various types of ropeways, and remarks as to their proper selection, by Mr. W. Carrington; determination of fire-damp in French collieries, by Mr. J. Coquillion; appliances for winding water, by Mr. Wm. Galloway; the detection and estimation of carbon monoxide in air by the flame-cap test, by Prof. F. Clowes; the Lake Superior iron ore region, by Mr. Horace V. Winchell.

THE January number of *Himmel und Erde* is devoted to several articles of general interest. Dr. Hecker, of Potsdam, describes how the small movements of the earth's surface are detected and measured. Two diagrams show clearly the details and general construction of the horizontal-pendulum, the instrument invented by von Rebeur-Paschwitz; while the reproductions from the actual photographic records explain for themselves the continual state of vibrations that is always occurring, and the occasional disturbances of larger amount. Dr. Zenker describes the extraordinary cold climate of Werchojansk (Siberia). The temperatures for each month, as obtained from the mean values up to the present time, are in degrees Centigrade—

Jan.	Feb.	March.	April.	May.	June.
−51·1	−45·8	−33·3	−13·6	2·0	12·6
July.	Aug.	Sept.	Oct.	Nov.	Dec.
15·6	10.2	2·6	−14·8	−39·8	−48·0

Prof. Dr. Fritz Frech concludes his series of articles on "Coral-reefs, and their share in the structure of the Earth's Crust." This series, we may remark, has been illustrated very profusely. "Eine Kulturbewegung in der Naturwissenschaft" is the title of a more brief article by Dr. Hallervorden, in Königsberg. In his concluding sentences he asks, "Why has Kant been forgotten? Ihn, den Schöpfer sittlicher Personlichkeit! Why has his house in Königsberg been long ago destroyed? Was it not like Goethe's, a relic of the nation—the nation?—of mankind, I ought to have said."

THE Zi-ka-wei Observatory, near Shanghai, has published a discussion of the disastrous typhoon which occurred in the Eastern Seas between July 22-25, 1896, in which the German gunboat *Iltis* was lost in the neighbourhood of the south-east Shantung promontory. This storm had first passed in the immediate neighbourhood of Shanghai, and the Rev. L. Froc has been able to collate a large amount of observations, both from ships which rode through the typhoon, and from land stations, which plainly show the extent and behaviour of the disturbance; and he has accompanied these observations with remarks which will be of practical use for the guidance of navigators. The storm took an unusual track, but was otherwise of regular constitution; the wind attained hurricane force, which was continued at some places for at least twelve hours. It is satisfactory to note that warning of its approach was given both by the Manila and Hong Kong Observatories, and that consequently two vessels, the *Pekin* and the *Yarra*, remained in port at Shanghai, and thereby in all probability avoided serious damage. We may mention that Dr. Doberck has also published an independent account of this storm in the *Hong Kong Government Gazette*.

THE additions to the Zoological Society's Gardens during the past week include a Patas Monkey (*Cercopithecus patas*) from West Africa, presented by Mr. A. F. Breysig; a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Mr. E. James; an Egyptian Monitor (*Varanus niloticus*) from the Transvaal, presented by Mr. D. E. Erasmus; a Red-eyed Ground Finch (*Pipilo erythrophthalmus*) from North America, deposited; a Tantalus Monkey (*Cercopithecus tantalus*, ♀?) from West Africa, a Black-headed Lemur (*Lemur brunneus*, ♂) from Madagascar, purchased.

OUR ASTRONOMICAL COLUMN.

THE PERIOD OF ROTATION OF JUPITER'S SPOTS.—Herr A. A. Nyland communicates to *Astronomischen Nachrichten* (No. 3401) his observations of Jupiter's markings, made at Utrecht with a refractor of 26 cm., and of focal length 320 cm. The object he had in view was to determine the period of rotation of this planet in different Jovian latitudes, and to accomplish this he observed the transits of eleven different spots across the smaller axis of the planet's disc. The results, as regards two spots, *a* and *b*, is given in the following tables, in which the second column shows the number of rotations, and the third the time of rotation.

Spot a.

1895-6.	No. Rotations.	Period of Rotation. h. m. s
Nov. 23—Dec. 10	... 41 ...	9 55 23·7
Dec. 10—Feb. 11	... 152 ...	32·0
Feb. 11—Mar. 10	... 68 ...	35·5
Mar. 10—Apr. 25	... 111 ...	32·1

Spot b.

1895-6.	No. Rotations.	Period of Rotation. h. m. s
Nov. 18—Dec. 22	... 82 ...	9 55 28·5
Dec. 22—Feb. 8	... 116 ...	34·6
Feb. 8—Mar. 13	... 82 ...	34·7
Mar. 13—Apr. 25	... 104 ...	38·2

It will be noticed that the spot *b* appeared to have a longer period of rotation than *a*, the former transiting after the latter according to the formula

1h. 45m. 1s. + 7·2s. × (*t* − 1. Jan. 1896 in days).

Observations of the "red spot" gave no indications of a diminution in the time of rotation. In the case of the other spots, it was found that they were too variable in their nature for such a determination to be made, as some split up into two and sometimes three parts, while others varied in their brilliancy and became hard to identify.

THE SPECTRUM OF ζ PUPPIS.—A Harvard College Observatory Circular (No. 16) contains some additional information to that which we gave in this column on November 26 of last year, concerning the spectrum of the star ζ Puppis. It was at first suggested that the second series of rhythmical lines was due to some unknown element, but it has now been concluded that such is not the case. A further investigation has shown that this series is very closely allied to that of hydrogen, and is probably due to that substance under conditions of temperature or pressure as yet unknown. A slightly modified form of Balmer's formula, namely,

$$\lambda = 3646{\cdot}1\,\frac{n^2}{n^2-16}$$

gives the wave-lengths of the lines of hydrogen if for *n* the even integers 6, 8, 10, 12, &c., be substituted. If in this formula the odd integers 5, 7, 9, 11, &c., be inserted for *n*, then the wave-lengths represent the second series of lines in ζ Puppis. The following brief table shows in the first column the value of *n*, in the second the computed wave-lengths by the above formula, and in the third the mean of two series of measured values.

n	Computed.	Observed Mean.
5 ...	10128·1 ...	—
7 ...	5413·9 ...	—
9 ...	4543·6 ...	—
11 ...	4201·7 ...	4200·4
13 ...	4027·4 ...	4026·8
15 ...	3925·2 ...	3924·8
17 ...	3859·8 ...	3858·7
19 ...	3815·2 ...	3815·9
21 ...	3783·4 ...	3783·4

Comparing the spectrum of ζ Puppis with other stellar spectra, the four lines between Hγ and Hθ have probable wave-lengths of 4472, 4544, 4633, and 4688. The first is a prominent Orion star line, while the second is well-marked, and is the line computed above when *n* = 9. All these four lines appear in 29 Canis Majoris, and three lines of the above series are measurable in the photograph of this star.

THE SPECTROSCOPIC BINARY α^1 GEMINORUM.—In the current January number of the *Astrophysical Journal*, Herrn. A. Belopolsky gives the results of his investigation of thirty-two spectrograms which he has obtained of the binary star α^1 Geminorum. This star required one hour's exposure, and a comparison with the spectrum of hydrogen was photographed at half-time. Using all the available data, Herrn. Belopolsky determined a series of values for the velocity in the line of sight, and after correction for the sun, found a periodic change, having a period of about 2·9 to 3·0 days. In the table which he gives, showing the velocity relative to the sun, he found that the curve of velocities satisfied either the first nine points (taken in January and February of 1896), with the exception of the eighth or the remaining twenty-four points, and that a single curve could not be drawn that would satisfy all the observations. This discrepancy, he remarks, suggested that the 2·91 days' period could not be used throughout the whole time covered by the observations. Applying a correction to the abscissæ for these dates, and drawing a fresh curve, he computed another series of velocities from the new elements. Even then slight discrepancies existed for these points, which, as he says, "cannot be explained with certainty at present." A possible cause is suggested in the rapid motion of the line of apsides in the direction of the orbital motion of the star, as was shown in Duner's analogous investigation of γ Cygni, in which a disturbing force, due to a flattening of the central body, exists.

NANSEN'S ARCTIC EXPEDITION.

A MEETING of the Royal Geographical Society was held on the evening of Monday, February 8, in the Albert Hall, when Dr. Fridtjof Nansen gave an account of the preliminary results of his great drift-journey in the *Fram* across the Polar area, and his sledge expedition northward. The Prince of Wales, the Duke and Duchess of York, and almost all the veteran British Arctic officers were present, while the great hall was crowded with the Fellows of the Society and their friends. Selections of Norwegian national music were played on the organ as the audience was arriving, and the appearance of Dr. Nansen and his companion, Lieut. Scott Hansen, on the platform was received with the greatest enthusiasm. Sir Clements Markham, K.C.B., F.R.S., President of the Society, introduced Dr. Nansen in a few words, and the explorer then addressed the meeting. During the address a large selection of photographs was shown by the lantern on a 40-foot screen; some of the pictures were taken by moonlight during the Arctic winter, and were extremely impressive, others were coloured reproductions of Dr. Nansen's sketches, including some fine sunset and aurora effects. Admiral Sir Leopold McClintock proposed, and Admiral Sir George Nares seconded, a vote of thanks for the address, in which they expressed their unqualified admiration of the manner in which Dr. Nansen had conducted his unique expedition. The Prince of Wales, as Vice-Patron of the Royal Geographical Society, then presented Dr. Nansen with the special gold medal of the Society, bearing the bust of the recipient on one side, and a representation of the *Fram* on the other. A copy of the medal in silver was presented to Lieut. Scott Hansen, and copies will be sent to the other members of the scientific staff of the *Fram*, while bronze replicas are given to the other members of the expedition. In thanking the Society for the medal, Dr. Nansen said that he had succeeded only by following the labours of his predecessors, the British Arctic officers, for whose heroism and resourcefulness he had the highest respect and admiration.

A large part of the address was necessarily occupied by describing the incidents of the journey already published in NATURE (vol. liv. p. 374). The following is a summary of the preliminary scientific results obtained by Dr. Nansen, and referred to during his address:—

Our expedition was intended to be purely a sea-expedition, the object of which was to drift with the drift-ice and keep clear of all land, so that we thought ourselves fortunate in avoiding the discovery of any extensive land. After passing through the Kara Sea the *Fram* skirted the north of Asia from the east of the Yenesei estuary to longitude 115° E. near the mouth of the Olenek. Off the western Taimyr peninsula an archipelago of small islands was encountered, through which it was difficult to find a passage; these I have named Nordenskiöld Islands, after

the man who showed us the way along the coast of Asia. It is difficult to distinguish mainland from island in passing along the coast, the map of which has been considerably altered by the observations on our voyage. The coast of the whole of the Chelyuskin peninsula northwards is very low, but inland we observed mountain ridges partly covered with snow, and probably some small glaciers. Without doubt the most important geographical discovery of the expedition was that concerning the polar basin itself. Formerly it had been supposed to be a comparatively shallow sea, a view in which I had concurred. We found that the sea in 79° N., north of the new Siberian Islands, suddenly became deeper than 100 fathoms, sank to depths of 1800 to 2000 fathoms, and such great depths were found continuously by the *Fram* during her entire drift north-west and west as far as the north of Spitzbergen. The polar basin thus appears to be a deep sea, forming a continuation northwards and eastwards of the depression in the North Atlantic Ocean. This deep sea probably extends further east than the New Siberian islands, as the *Jeannette* found the depth increasing every time the drift carried her to the northward.

I think we can safely say that little or no land can lie on the Asiatic side of the pole, as in the sledge-journey north of the *Fram's* route we found the ice drifting with greater freedom than further south, which would not likely be the case if there was much land to restrict the movement. There is, on the other hand, a probability of the existence of land to a considerable extent on the American side of the pole, where islands, and islands of some importance, may be expected to be found north of the boundary known at present. A closer examination of these parts we must hope will be undertaken in the not too distant future.

The drift of the *Fram* showed that a deep sea lay along the north of Franz Josef Land, proving that that land has not the great extension northward which it was hoped to have. This discovery confirms Sir Clements Markham's prediction that "Franz Josef Land seems to be part of the Spitzbergen group, rising out of the same shallow sea, with deeper water to the north." The geological evidence confirms this view, and in those parts which Johansen and I would have visited had we not fallen in with Jackson; the Jackson-Harmsworth expedition will no doubt have many interesting discoveries to make. From the disagreement of our discoveries with Payer's map, we were at first led to believe that our watches must be altogether wrong, and that we had come to a land further west; it was only after comparing our watches with Jackson's, that I came to the conclusion that Payer's map was wrong. Dr. Copeland is now engaged in re-calculating Payer's positions, and finds his work particularly good; the error most probably arose through his mistaking banks of mist on which the sun was shining for a great glacier-covered land. Such a mistake is very difficult to avoid in certain atmospheric conditions

In the course of the voyage along the coast of Siberia abundant evidence of the former existence of a great ice-sheet was forthcoming, and the appearances could not be explained by reference to local glaciers. For instance, the land on the east side of the Chelyuskin peninsula, where I went reindeer-shooting one day, was a very undulating clay plain, over which was strewn a multitude of big boulders of various rocks, which could with difficulty be explained otherwise than as being material brought by an extensive ice-sheet. The fact that I found an indication of stratification in several places can hardly be regarded as an argument against its moraine-like character, as there are incontestable moraines in the south of Norway which show distinct stratification. The exemption from an ice-sheet, so long claimed for Siberia, can no longer be maintained.

The microscopic examination of the numerous specimens of sea-bottoms obtained by our soundings, proved that they differ essentially from the samples taken from the North Atlantic Ocean, as they are wanting in the characteristic organisms. The arctic deep-sea mud was found to be particularly deficient in carbonates, and appears to consist chiefly of mineral components; but so far only very imperfect examinations of these deposits have been made.

During our journey we had abundant evidence of the reality of the ice-drift across the polar area, on the faith in which the expedition had been planned. Earthy matter was found on the ice as far north as 86°, and driftwood also. I remember one day far north, during Johansen's and my journey over the ice, our astonishment at seeing a large piece of timber projecting from the ice; it hailed, perhaps, from the interior of Siberia, and was on its way to the Eskimo of Greenland. The only thing we could do was to cut our initials on it, with the date and latitude. The cause of the drift is, first of all, the wind, the prevailing direction of which is from the Siberian Sea towards the North Atlantic Ocean. As the wind varies, the drift varies also; but it was always strongest when towards the north and west, and feeblest when it turned towards south and east. Most progress was made in the winter, least in summer, when northerly winds were relatively common. I believe that when the records are worked up it will be possible to demonstrate that there was a slight current in the water under the ice, setting in the prevailing direction, or perhaps a little to the northward of the prevailing wind. The massive ice-cap, which many polar explorers have believed to cover the polar area, has been shattered; instead of it we have the ever-wandering ice-fields, like a link in the eternal round of nature.

The ice does not grow to any great thickness by direct freezing; something under four metres was the greatest seen; but, of course, it becomes very much thicker by the piling up of broken ice-sheets driven together and mounting one above another. The pressure of the ice was found to be largely dependent on the tidal current, especially on the margin of the polar ice-fields. There the periods of great pressure occurred regularly about new moon and full moon, the former being the greater. The worst ice-pressures encountered by the *Fram* were when the wind suddenly changed after having been long steady, when smaller masses of ice would be driven by the wind against the greater masses moving on by their own momentum.

The temperature of the water at various depths beneath the ice was of special interest. Even as far east as the sea north of the New Siberian Islands I found undoubted traces of a warm current. The surface water of the entire polar basin is doubtless very cold, between $-1°5$ and $-1°6$ C., the freezing point of sea-water. Beneath this cold layer at depths of 200 metres, I suddenly found warm water, the temperature rising to $+0°5$, or even $+0°8$ C. At a greater depth the temperature varied somewhat, but remained nearly constant to 400 or 500 metres, after which it slowly sank until the bottom was reached, without, however, becoming so cold as at the surface. The air temperatures were, as was anticipated, not so low as in Siberia, doubtless owing to the influence of the deep underlying sea. The minimum we found ($-53°$ C.) is not immoderately low, recollecting that at Verkhoyansk $-68°$ has been recorded. The winds in the far north were not very strong, seldom amounting to a gale; but this climate entirely changed on the southward journey, and in the winter quarters on Franz Josef Land a succession of furious gales howled around us continually.

There were exceptional opportunities of observing the aurora, and amongst other curious phenomena the heavens were often shrouded with a light luminous veil, through which it was difficult to see the Milky Way. The aurora was found to be much more common in very high latitudes than it was formerly supposed to be.

Animal life was abundantly observed both in the form of small marine organisms, especially crustacea, and larger creatures. Narwhal were seen in shoals up to nearly 85° N., and seals were also frequently seen in summer. Bears were shot north of 84°, and fox tracks seen in 85° N. Near Hvittenland east of Franz Josef Land, the probable nesting-place of the rosy gull was found. The fresh-water pools on the ice in summer swarmed with diatoms and other algæ.

The expedition found much of value in considering future travel. The type of vessel embodied in the *Fram* was found perfect, resisting all ice pressures, and the ship was as sound at the end as at the beginning. Another drifting expedition should enter the ice much further east, entering by Bering Strait, and the ship should be equipped with greater laboratory accommodation. Nothing remains to be done for preserving health; the company on the *Fram* were never seriously ill, and even on the march over the ice I personally increased 22 lbs. in weight. There was never the faintest indication of scurvy.

THE LEGENDARY HISTORY OF FUNAFUTI, ELLICE GROUP.[1]

THE first king of Funafuti was Teromatua (? Tilimatua), but who he was or where he came from is not known; it is certain, however, he was here before the arrival of the Kauga, people who swam to this island from Samoa, which means, I

[1] This is the story of Funafuti, so far as I could learn it from the King Erivara and our interpreter, the white trader O Brian.

take it, Samoans who were wrecked from a canoe and afterwards swam ashore. The Kauga were much respected. Toa, a piece of land in Funafuti, is named after one of them, and the southernmost island, Tuaeriki, after another: after death they were worshipped as spirits.

The only son of Terematua was Kitosuga, and he had one son Tiloa, who likewise had an only son Tilotu. In the time of Tilotu a subordinate king or chief was appointed, by name Paolau. What relationship by blood, or whether any existed, between Tilotu and Paolau the king could not tell me; a very old woman, as he said over 100 years old, who had instructed him in the history of his predecessors, had not informed him on this point.

Paolau became king after Tilotu's death, and Tilotu's children became sub-kings or chiefs.

Paolau was killed by his younger brother Nigi, who aspired to the throne. When Nigi drew near to Paolau the latter said, "Are you going to kill me?" Nigi pointed to the rising moon and said, "My head is there," and then to the place where it would set, adding "your head is there!" and killed him.

Nigi then became king; after his death he was succeeded by Tukalamiti, whose parentage is not known; he was probably a son of either Paolau or Nigi—possibly of Paolau's, for there were two branches of the royal family, and when one king died his successor was generally chosen from the other branch.

It is not known whether this was a friendly arrangement or not. Then another Paolau became head king, and Masaleika, his brother, sub-king; the latter never attained the chief dignity, as he was killed by Tauvasa. Paolau fell sick on the southernmost island, and Tauvasa sent people in canoes to kill him.

Paolau and his people went to see what the canoes had come for, and invited the crews to stay the night with them. This they did, and during the night Paolau's daughter discovered their purpose and warned her father.

The leader of the expedition, Salaiki, a brother of Paolau's, was then set upon and killed. Paolau retained his kingship, and Tauvasi remained chief till the illness of the former proved fatal, as it did soon after the attempt upon his life. Tauvasi then became king. He seems to have been a good ruler, and signalised his reign by dividing the land, which had hitherto been held in common, and fairly apportioning it amongst the people. The history of the kings now becomes mixed up with that of the priesthood. In early times the people worshipped thunder and lightning and the powers of nature, as well as birds and fishes. This was followed by the worship of spirits, one of whom was named Tufakala after a particular kind of seagull. There then arose priests or spirit-masters (vakatua).

One of the earliest, if not the first, was Erivara, evidently a very masterful person. He abolished the ancient worship, taking the dead Firapu, or his spirit, the father of Tauvasi, for his first god. Firapu was a hero whose death is shrouded in mystery—he and his daughter Mumu had left Funafuti in their canoe on a voyage to the Gilbert Islands, and had never returned. As time went on descendants of Firapu after death were added to the list of spirits, and worshipped as subordinate deities.

Besides this worship of spirits there was also a kind of fetish worship, also introduced by Erivara. Erivara in his sleep visited the other world, and made the acquaintance of seven spirits, who showed him a wonderful object and directed him on returning to earth to make a copy after its fashion, giving him full instructions how to proceed. On his return to earth, more prosaically when he awoke, he sent one of the people to dive outside the reef for a red stone. This was procured and brought to him. He wound round it a dress of pandanus leaves—red, white and black, some fathoms long, and placed it inside a cage shaped like a hen-coop. This was called the Teo.

If a parishioner was sick, Erivara took the stone from its wrappings, talked to it, charmed it with rhymes, and applied it to the sick man. Another fetish was a hat, the size and shape of a hogshead cask, made up of red, white and black fandango (Pandanus) leaves, and adorned with white shells. This was called the Puluo, and was said to be the hat of Firapu. I think this was kept in the spirits-house, but the Teo was kept in a separate hut—the charm-house.

When the people wanted to catch fish, the Puluo was brought out of the spirits-house by the king's orders, and the whole community walked three times round the house, bearing the Puluo in front. The women followed, stark naked, and the men, who belaboured one another with sticks; the children completed the procession.

The charm-house was set round with a great number of sharp-pointed stakes, and when a catch of fish was made the people were required to take it to the spirit-master and lay it down in front of the charm-house, not the king's. The charmer then picked out the finest fish, impaling each, as he selected it, on one of the stakes and dedicating it in a loud chant to the particular spirit—Faiologata, Tamaiki, Fijiroa, Tongatumatua, Firapu, Sasaka, or some other to which the post was sacred. When the dedication was complete, the people shared the remainder between them. The sacrifice was divided between the priest and his relations.

This was a pretty fair source of income; but the charmer could not live on fish alone, and so he had other methods by which coconuts, taro, and the rest were added to them.

The spirits would come to him and give him warning that some one was going to be sick; the spirit-master would then send for this person, and take him to the charm-house to be charmed. This house was a square hut with a fire burning in the centre, and on the entrance of the threatened man this was made to smoke so that the spirit should not be able to see him. The spirit-master was provided with two young coconuts and young white leaves of the coco palm. He rubbed oil on one of the nuts, rubbed his nose against one eye, whispered to it, and then turned it away from him. Crossing his hands he gave it a good spin, and watched how it came to rest; if when it stopped it pointed sideways or away from him, the spirit was very angry and the man would be very ill; if, on the contrary, it pointed to him, the spirit was not vexed.

Of course these performances meant taro and coconuts.

In case the man was to be taxed pretty severely the spirit would of course be angry, and there would be other charms required to mollify him, and these had to be paid for. If a man were really ill the spirit-master would come and wave a staff, with a bunch of coloured pandanus leaves at the end, over him, or he would thrust this staff like a spear through a coconut, or he would try the smoking and the Teo treatment.

In any case the medical attendance was very expensive, and the patient's friends and relatives had to gather together a good deal of food to keep the spirit-master and his friends while the case was in progress.

Erivara, the first devil-master, was so fertile in inventions of this kind, that I could not believe he had owed them all to his own unaided powers, and I inquired therefore if he was accustomed to travel much, and was told he had visited at various times Nukulailai, Vaitapu and Nukufetau, neighbouring islands of the group, as well as the Gilberts. This in itself, however, is no proof that he was a plagiarist.

Erivara was, notwithstanding, a great benefactor to the island; the coconut palms were few, and food was scarce, so he organised expeditions to the Gilbert Islands, and brought back in canoes a great quantity of nuts; the people extracted the cotyledon from these for food, which shows they were very hard-up, and then planted them. The whole of the islets of Funafuti were planted in this way under his direction—a great achievement.

On the other hand, Erivara broke up the ancient laws of the kings, and upset the distribution of the land, dividing it afresh between the king (erikitutu) and thirty or more sub-kings of his own creation (erikitabua). Hence arose disputes as to the ownership of the land, which persist even to the present day. There is this excuse to be made for Erivara, that by reason of his planting the land acquired the chief value that it possesses. Still he might have shown a little more consideration for those families which had no man at the head, only old women; he was oppressive towards the weak.

During the time of Erivara Tauvasi died, and his son Sirimiau became king, after him his son Dili succeeded, and after Dili Sukumuni, after Sukumuni Tarafo, belonging to another branch of the Tauvasi family, succeeded to the headship; he was followed by Taturi, his son, and Taturi by his brother Teriki. Teriki was followed by Matavai, who was deposed by reason of the ulcers with which he was afflicted, the evil smell of which made it impossible for people to sit in the house with him. Jacopa, his eldest son, replaced him; then Manu, his second son; and finally Erivara, the reigning monarch, the youngest of Matavai's three sons. Erivara is a very intelligent and dignified old man, say fifty years of age, every inch a king, though shorn of all power. Our High Commissioner is the chief governor, and makes laws for the island; but the true master here is the native missionary Simona, who is a Christian spirit-master of a very friendly disposition. The ancient religion

received its death-blow about thirty years ago, not from a missionary, but from a white trader, O'Brian, now living on the island, who accomplished its overthrow, not from any religious motive, but because the ancient religion took up much of the time which he thought, rightly or wrongly, should be given to collecting copra for him. He told the natives that the captain of the vessel trading with him threatened on his return to shoot every man, woman and child if they did not destroy the spirit and fetish houses. "And do you think he will do it?" they asked. "Undoubtedly," was the reply. So they were terribly frightened, and some wished to destroy the houses, and others, under the leadership of the priest, were opposed. Three men-friends of O'Brian's were in favour, and they went into the charm-house, took down the Teo, polluted it and put it back. There was a great noise when the deed was discovered, and suspicion fell on these three men and O'Brian. The three men left the island and went to Nukulailai, and of course were thus self-condemned. The spirit-master accordingly performed his charms, and told the people that these three men were now dead. One of the three men, Leveri, had a twin brother who remained in Funafuti after the flight of Leveri, and he was terribly grieved over his brother's death; the other men also were much regretted, and the whole population went into mourning—cutting off their hair, they made necklaces of it to wear round their necks, abstained from eating taro, and in other ways showed their grief.

One day, however, Leveri returned in a ship; the people could not credit it, and said it must be his spirit. Leveri, however, cried out to them in his own proper voice, and they had then no doubt that he was alive; they asked him about the other two men, and learnt that they also were alive and well, and meant soon to return. Then there was great uproar, and the people cried, "Burn the devil's house." O'Brian did not wait for further orders, but went off with a half-caste and set both the devil's and the charm house on fire. The spirit-master, or devil-master, seized the Teo and escaped with it in his canoe to the lagoon. But O'Brian took his double-barrelled gun and went after him, and threatened to shoot him if he did not bring it back: knowing well that if this devil-master escaped with the Teo, the people would begin to worship it again on the first opportunity. The devil-master came back, and O'Brian took the Teo, unwound the stone from its wrappings—it was a red stone from six to eight inches long—and dashed it in pieces on the ground. Then he fired his gun through the roof of the burning house and exclaimed, "There goes your devil up in the air! See him!" And all the people said "Tschah!" an expression of great surprise.

The devil-master threatened proceedings from the next world. "Now," said he and his friends, "never more any turtles, no bonitos, no fish in lagoon."

There was a devil's house on the northern island, and O'Brian and Matika went in their canoe to burn that down too; on the way they got hundreds of black fish, and brought them back to the islanders. The people said, "God was sorry for the devil, and gave these fish to atone." So they gave them away (to the devil-master?).

The turtle is taboo to all but the king. When one is caught it is brought to the king, who recites the following formula over it before cutting it up:—

Te ailu o te fonu
The body of the turtle

Te ika mua e soa
The fore paddles are fellows (a pair)

Te ika muti e soa
The hind paddles are a pair

Te vaesiosio e soa
The lungs are a pair

Te alaga mua e soa
The arms are a pair

Te alaga muti e soa
The legs are a pair

Te matua tinae e soa
The breast is a pair

Te puloa e soa
The belly is a pair

Te laukape e soa
The back is a pair

Te matua lua e soa
The small guts are a pair

Te lakau e soa
The great intestine is a pair

Te fatumava e soa
The liver is a pair

Te ate e soa
The fat under the armpits is a pair

Te mama e kiukiu te fua
. . . . .

He then divides it among himself and his relatives.

I have attempted, with the help of the natives, to translate all the lines except the last, which O'Brian told me meant "the eggs are thousands and thousands." The formula as I give it is copied from the writing of a native scribe, who took it down in our presence as the king recited it.

July 19, 1896. W. J. SOLLAS.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following have been elected to the University Mathematical Scholarships and Exhibition for 1897:—To the Senior Mathematical Scholarship: E. E. Roberts (Corpus Christi College). *Proxime accessit:* E. Lawton (Corpus Christi College), to whom the Examiners have awarded Lady Herschel's Book for Astronomy. To the Junior Mathematical Scholarship: W. M. Roberts (scholar of Corpus Christi College). *Proxime accessit:* R. F. McNeile (scholar of Balliol College).

Mr. C. L. Shadwell, Fellow of Oriel College, has been appointed a Curator of the Botanic Garden, in place of Mr. F. T. Richards.

The General Medical Council has decided not to register as medical students those who have only passed Responsions. They will henceforth require a knowledge of Algebra up to simple equations, and of Euclid, Books I.-III., with easy deductions, in addition to the ordinary subjects of the examination. Steps are being taken to meet these requirements.

The Junior Scientific Club met on February 3, Mr. A. W. Brown (Christ Church), President, in the chair. Mr. Percy Elford exhibited a series of specimens illustrating the evolution of the match. Mr. A. E. Boycott (Oriel) read a valuable and interesting paper on shell colouration in British extra-marine mollusca; and Mr. B. H. Rolfe (Merton) discussed the effect of climate on building-stone. The President announced that the first volume of "Robert Boyle Lectures" would shortly be published.

The Professorship of Geology is still vacant. At present arrangements are being made for the instruction of those who wish to study geology at the Museum. The new Professor will in all probability be appointed in the course of the present term.

Mr. F. F. Fison has been elected to a Casberd Scholarship in Mathematics at St. John's College.

CAMBRIDGE.—The degree of Master of Arts, *honoris causa*, is to be conferred on Dr. A. A. Kanthack, Deputy-Professor of Pathology. The Senate has assigned a stipend of £250 to Dr. Joseph Griffiths while he is discharging the duties of the Professor of Surgery during the vacancy of the chair. The Senate has also made a grant of £50 to the University Lecturer in Geography (Mr. Yule-Oldham) for additional maps and apparatus.

Dr. D. H. Scott, F.R.S., has been appointed an Elector to the chair of Botany; Mr. J. J. H. Teall, F.R.S., an Elector to the chair of Geology; Sir W. H. Flower, F.R.S., an Elector to the chair of Zoology; Dr. A. S. Lea, F.R.S., an Elector to the chair of Physiology; and Dr. J. Sully, an Elector to the chair of Mental Philosophy.

LORD HERSCHELL recently opened new technical schools at Swindon. They are built upon a site generously presented by Major Rolleston, at a cost of £12,000, towards which the New Swindon District Council contribute £7500, the Wilts County Council £3500, and the Science and Art Department £1000.

THE National Association of Manual Training Teachers has issued a circular letter asking teachers of manual training, "Whether the making of apparatus and instruments for physics (as suggested in the Physics' Syllabus, Form 74, of the Science and Art Department) interferes educationally with manual training?"

THE Cornwall Sea Fisheries Committee have resolved to apply to the County Council to sanction a salary of £250 a year, with an additional £100 for travelling expenses, in con-

nection with the post of lecturer to the Committee. There is a difficulty in obtaining a competent man at the salary originally decided upon.

THE Technical Education Committee of the Berkshire County Council have advised the Council to establish four agricultural exhibitions of the value of £35 each, to be open to boys between fourteen and sixteen, and tenable for two years at the Dauntsey Agricultural School, which has been established to give a thoroughly practical instruction in the various branches of farm work.

THE Committee of Graduates of the University of London unanimously resolved, at a recent meeting :— "That the Committee of Graduates of the University of London in favour of the scheme of Lord Cowper's Commission, express the earnest hope that her Majesty's Government will again introduce a Bill for the creation of a statutory commission for the reconstitution of the University of London, and assure the Government that such a measure will have their active support."

THE Chairman of the Leicestershire Technical Education Committee informed the County Council, at their meeting on the 3rd inst., that at the present time there was not a single student from Leicestershire at the Midland Dairy Institute, though there were as many as forty last spring. This is owing to the fact that Leicestershire only interests itself in the practice of cheese-making, which cannot be satisfactorily carried out in the winter. But since there are so many branches of agriculture which can be properly studied during the winter months, it seems a misfortune that Leicestershire should reap no advantage from its contributions to the support of the Dairy Institute during so large a part of the year.

THE following are among recent appointments :—Dr. Johann Rückert to be professor of anatomy in the University of Munich ; Dr. Liznar to be professor of meteorology and terrestrial magnetism in the Technical High School at Vienna ; Dr. R. Schüssler to be professor of geometry in the Technical High School at Graz ; Dr. C. J. Martin to be provisionally the successor to Dr. G. B. Halford as professor of physiology in the University of Sydney ; Dr. Arnaldo Maggiora to be professor of experimental hygiene in Modena University ; Dr. A. Serafina to be professor of experimental hygiene in the University of Padua. Among recent calls are :—Dr. Felix Auerbach, of Jena, to be professor of physics at Strasburg ; Dr. Franz, assistant in the Observatory of Königsberg, to be associate professor of astronomy at Breslau.

IT is announced in the *Lancet*, that the present Lord Rector of the University of St. Andrews—the Marquis of Bute—has undertaken to erect at his own cost, under certain conditions, four new laboratories, lecture-rooms, museums, work-rooms, &c., for the departments of anatomy, physiology, materia medica, and botany. These laboratories will be provided with all modern appliances for teaching and research purposes. They will form a most important addition to the existing natural philosophy, natural history, and chemical departments. As the laboratories are to be built apart from the existing colleges on ground of their own, they will, of necessity, form the headquarters of the extended medical school there, which school will henceforth be known as the "Bute School of Medicine," in commemoration of the generous donour.

AT a recent meeting of the Senate of the University of Wales, the question of fellowships, scholarships, exhibitions and prizes, to be established in connection with the University, was again discussed. The Senate recommended that there should be four fellowships of at least £100 per annum, tenable for two years, with possible renewal for a third year in recognition of exceptional merit. The prizes will be open both to graduates and undergraduates, and will be awarded for excellence of attainment in departments of study recognised by the University. The fellowships, scholarships, and exhibitions will be confined to graduates of the University. Fellowships will be only conferred for very distinguished merit, and will be tenable on condition of residence at some approved seat of learning or research, and on the active pursuit of original investigation. They will be awarded by the Court on the recommendation of the Senate, the Senate acting on the recommendation of a small Standing Committee specially appointed for this purpose. The Standing Committee will require information as to the subjects of research or advanced study to which candidates propose to devote themselves, and (in the event of their election) receive from time to time reports as to their work and progress.

WE are glad that the Prince of Wales has again shown his interest in the excellent work of the Technical Education Board of the London County Council, by presiding at the distribution of prizes and certificates on Friday last. The magnitude of the work of the Board is shown by the fact that the number of scholars and exhibitioners who were elected in 1896 is 893, made up as follows :—5 senior county scholars ; 70 intermediate county scholars ; 588 junior county scholars ; 18 schools of art scholars ; 21 artisan art scholars ; 95 junior artisan evening art exhibitioners ; 85 evening science exhibitioners ; 2 horticultural scholars ; 9 domestic economy training scholars. The total pecuniary value of these scholarships and exhibitions amounts to about £40,000. The amount placed at the disposal of the Board for the coming year is £150,000. In the course of an address at the close of the presentation of the certificates, the Prince of Wales pointed out that the Technical Education Board has made grants to University College, King's College, and Bedford College, under such conditions as are calculated to place the highest technical teaching of these institutions within the reach of those students who could not otherwise afford to devote several of the best years of their lives to a course of University study. Under these conditions evening classes in certain subjects, especially in those connected with mechanical and electrical engineering, have been conducted on precisely the same lines as the day classes, and by the same professors and lecturers ; and on Saturdays the professors have undertaken to give instruction in several classes to teachers, who thus enjoy the advantages of all the resources of the best University institutions.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 21.—"Experiments on Examination of the Peripheral Distribution of the Fibres of the Posterior Roots of some Spinal Nerves, Part II." By C. S. Sherrington, F.R.S., Holt Professor of Physiology, University College, Liverpool. Received November 12, 1896.

This paper is in continuation of one brought before the Society in 1892, and published in *Phil. Trans.*, vol. 184, B. The communication is divided into four sections. In Section I. the field of peripheral distribution of each root is described from the Vth cervical to the lower end of the brachial region. Particular attention was paid to the question of the skin-fields of the several divisions, ophthalmic, maxillary, and mandibular of the cranial Vth, in order to see if the fields possessed the characters of segmental skin-fields, or those of peripheral nerve-trunk skin-fields. They were found to conform with the latter, not with the former. A curious relation of the posterior edge of the field of the Vth to the external ear is found to exist, indicating that the position of the visceral cleft is still adhered to as a boundary line for the field of the trigeminus. The sense of taste as well as of touch is found to be destroyed in the anterior two-thirds of the tongue after intracranial section of the Vth ; this makes it extremely doubtful whether the corda tympani can have gustatory functions in the monkey, as has been believed in some cases in man. No loss of eye-movements, or interference with them, has been found to result from intracranial section of the Vth.

After cranial Vth and all the upper cervical posterior roots have been severed, there still persists a small field of sentient skin, which includes the external auditory meatus and a part of the pinna. This field, although not corresponding to the situation given by anthropotomists to the distribution of the auricular branch of the vagus, may come either from it or the glossopharyngeal. It presents interest as being the only field representing the whole cutaneous distribution of a nerve, which does not conform with the rules of zonal distribution holding good in the case of each of the other nerve-roots examined, and these now include the whole craniospinal series. The posterior root of the 1st cervical nerve has a skin-field in the cat, which includes the pinna. The posterior root of the same nerve in Macacus has no skin-field at all, its skin-field having apparently been included in the IInd cervical of Macacus, not in the cranial Vth. The root fields contributing to the surface of the brachial limb are IIIrd, IVth, Vth, VIth, VIIth, and VIIIth cervical,

and Ist, IInd, and IIIrd thoracic. Of these, the VIIIth cervical is the only one which includes the whole of the surface of the free apex of the limb; its distribution in this respect closely resembles that of the VIth lumbar sensory root in the pelvic limb.

The IInd section of the communication deals with the degree of conformity between the distribution of the spinal ganglion fibres in the skin and their distribution in the underlying deep tissues of the limb. It is shown that, although the *skin* fields of the ganglia are in the middle of the limb region dislocated from the median line of the body, the fibres of the root ganglion are nevertheless, when their deep distribution is taken into account, distributed to a complete ray of tissue extending in an unbroken fashion from the median plane of the body out along the limb to (in the case of the nerves, extending furthest into the limb) the very apex of it. This distribution conforms, therefore, with that shown in a previous paper to be typical of the distribution of the ventral (motor) root. The distinction is not, therefore, as between *afferent* and *efferent*, but as between *cutaneous* and *muscular*. A detailed analysis of the distribution of the deep sensory fibres is in this paper carried out for the VIth lumbar spinal ganglion of *Macacus rhesus*; this ganglion was chosen because its skin-field, occupying the free apex of the lower limb, is one as far dislocated from the median line of the body as any in the whole spinal series, and presents, therefore, the greatest apparent discrepancy between the distribution of its afferent and efferent roots. A comparison of the distribution of the afferent and efferent roots in this (VIth lumbar) nerve was made by means of the Wallerian method; the results show the peripheral distribution of the two to be minutely similar. From this, and from other observations given, the rule is put forward as a definitely established one that the sensory nerves of a skeletal muscle in all cases derive from the spinal ganglion (or ganglia) corresponding segmentally with that (or those) containing the motor cells, whence issue motor nerve-fibres to the muscle. The reflex arc, in which the afferent and efferent nerve-cells innervating a muscle are components, need not, therefore, as far as anatomical composition is concerned, involve irradiation through more than a single spinal segment.

Section III. deals with general features of arrangement recognisable in the distribution of the roots.—Comparison between the human brachial plexus and that of Macacus is made, and it is pointed out that the human plexus is slightly prefixed, as compared with that of Macacus.

Finally, in Section IV., various spinal reactions are examined, especially with reference to their effects upon the size and other features of the areas of the root-fields, &c., and the results collated and discussed.

"Cataleptoid Reflexes in the Monkey." By C. S. Sherrington, F.R.S., Holt Professor of Physiology, University College, Liverpool. Received December 29, 1896.

The reflex movements, the subject of this note, are of extremely prolonged duration, and absolutely devoid of clonic or alternating character. If the cerebral hemispheres be removed *e.g.* from a monkey, and if a finger of one of the monkey's hands be stimulated, for instance, by dipping it into a cup of hot water, there results an extensive reflex reaction involving movement of the whole upper limb. The wrist is extended, the elbow flexed, the shoulder protracted, the upper arm being drawn forward and somewhat across the chest. The movement occurs after a variable and usually prolonged period of latent excitation. The movement, although it may be fairly rapid, strikes the observer each time as perfectly deliberate; it is of curiously steady and "smooth" performance. Sometimes it is carried out quite slowly, and then, as a rule, the extent of it is less ample. The most striking feature of the reflex is, however, that when the actual movement has been accomplished *the contraction of the muscles employed in it does not cease or become superseded by the action of another group, but is continued even for ten and twenty minutes at a time.* The new attitude assumed by the limb is maintained, and that too without clonus or even tremor. In the instance cited, namely, that of the fore limb, the posture assumed suggests the taking of a forward step in quadrapedal progression, and in that posture the animal will remain for a quarter of an hour at a time.

The degree of, for instance, flexion assumed in the new posture seems much dependent on the intensity and duration of the stimulus applied. If the degree is extreme, the attitude of the limb may not be maintained to its full extent for the time mentioned; thus, the elbow, at first fully flexed, will in the course of a minute or so be found to have opened somewhat. This opening can be often seen to occur *per saltum*, as it were, but the steps are quite small, and recurrent at unequal intervals of between perhaps a quarter of a minute and a minute. After some relaxation from the extreme phase of the posture has taken place, the less pronounced attitude, *e.g.* semiflexion at the elbow, may persist without alteration obvious to inspection for ten minutes or more. Apart from the occasional step-like relaxations, the contraction of the muscles is so steady as to give an even line when registered by the myograph. A renewed stimulation of the finger excites further flexion, which is maintained as before in the way above described. The posture can be set aside without difficulty by taking hold of the limb and unbending it; the resistance felt in the process of so doing is slight; the posture thus broken down is not reassumed when the limb is then released.

Analogous results are obtainable on the hind limb. Hot water applied to a toe evokes always, so far as I have seen, flexion of ankle and knee; usually of hip also. This movement is "deliberately" executed, and always institutes a maintained posture.

Not the least interesting part of the reflexes under consideration is a remarkable glimpse which they allow into the scope of reflex inhibition as regards the coordinate of movements of the limbs. Although the posture taken up by the right fore limb consequent upon excitation of a finger is symmetrically duplicated by the left limb when both hands are simultaneously stimulated, the effect of excitation of the two hands does not lead to symmetrical posture if the excitation be not synchronous but successive. If when the right arm has already assumed its posture in response to an excitation of the right hand, the left hand be stimulated, there results, while the left arm in obedience to the excitation is lifted and placed in the flexed posture, an immediate and, if the stimulus be at all more than slight, complete relaxation of the right arm. The right arm drops flaccid, while the left is raised and maintained in the raised attitude. Similarly, excitation of the right foot breaks down the posture assumed by the right arm, and conversely, and even more easily, stimulation of the right hand breaks down a posture assumed by the right leg. Again, a nip of the right pinna causes relinquishment of a posture assumed by the right arm or by the right leg. If the right pinna is pinched when both arms are in this cataleptoid posture, complete inhibition can be readily exerted on the right arm, but usually only partial relinquishment can be induced in the left arm. To exert complete inhibition upon the posture of the left arm, the pinna pinched must be that of the left side. Similarly the posture reflexly evoked by appropriate stimulation of either hind limb can be inhibited by excitation of either pinna or of either fore limb, but predominantly by pinna and fore limb of the same side as the limb to be inhibited. The inhibition of the hind limb is much more easily elicited from the opposite hind limb than from the opposite fore limb or opposite ear. I have never yet seen it obtained diagonally upon the fore limb from the opposite hind limb.

February 4.—"On Lunar Periodicities in Earthquake Frequency." By C. G. Knott, Lecturer on Applied Mathematics, Edinburgh University (formerly Professor of Physics, Imperial University, Japan). Received November 4, 1896.

General Conclusions.—The conclusions are summarised under eight heads.

(*a*) There is evidence that the earthquake frequency in Japan is subject to a periodicity associated with the lunar day.

(*b*) The lunar half-daily period is particularly in evidence, both by reason of its relative prominence and the regularity with which, in each of two groups of the several seismic districts, its phase falls in relation to the time of meridian passage of the moon.

(*c*) There is no certain evidence that the loading and unloading due to the flow and ebb of ocean tides have any effect on seismic frequency.

(*d*) Hence we must look to the direct tidal stress of the moon, in its daily change, as the most probable cause of a range in frequency which does not exceed 6 per cent. of the average frequency.

(*e*) There is distinct evidence, both as regards amplitude and phase, of a fortnightly periodicity associated with the times of conjunction and opposition of the sun and moon.

(*f*) No definite conclusion can be drawn from the apparent monthly and fortnightly periodicities which seem to be

associated with the periodic changes in the moon's distance and declination, for the simple reason that fully as prominent harmonic components exist when the statistics are analysed according to the periodic change in the moon's position relative to the *ecliptic*, and with this particular period no tidal stresses can be directly associated.

(*g*) Nevertheless, the value of the phase lends some support to the view that there is a real connection between the change in the moon's distance and earthquake frequency, since the maximum frequency falls near the time of perigee.

(*h*) These conclusions have, in comparison with previous similar investigations, a peculiar value, inasmuch as they are based upon accurate statistics of fully 7000 earthquakes occurring within eight years in a limited part of the earth's crust, throughout which the seismic conditions may be assumed to be fairly similar from point to point.

February 4.—"Some Experiments on Helium." By Morris W. Travers. Communicated by Prof. W. Ramsay, F.R.S. Received December 30, 1896.

Geological Society, January 20.—Dr. Henry Hicks, F.R.S., President, in the chair.—On glacial phenomena of Palæozoic Age in the Varanger Fiord, by Aubrey Strahan. The Gaisa beds of the Varanger Fiord consist of slightly altered quartz-grits, with red sandstones and shales, and rest upon a deeply denuded surface of the metamorphic rocks. In a section, first noticed by Dr. Reusch, a heterogeneous mixture of grit and clay with boulders of granitic and other rocks is seen to be intercalated between the quartz-grits, the bedding of the overlying grit proving that this boulder-rock was contemporaneously formed, and not subsequently wedged in. The surface of the grit below the rock is characteristically glaciated. Proof was given that the striated surface is not the floor of a thrust-plane, and that the boulder-rock is not a fault-breccia or a crush-conglomerate, but a "till." In the absence of fossils the Gaisa formation was doubtfully assigned to an early Palæozoic age. It exhibits the same sedimentary characters as the rocks of later date in other parts of the world in which glacial phenomena have been observed. The glacial episode was attributed to a temporary change of climate rather than to the high latitude in which the section lies.—The raised beaches and glacial deposits of the Varanger Fiord, by Aubrey Strahan. The raised beaches range up to nearly 300 feet above the sea. Though a number of impersistent shingle-banks occur at various heights, the highest is constant, and can be traced along the same level either as a shingly terrace or by a zone of wave-worn rocks. Evidence is furnished by the relative size of different parts of the beach that the prevalent wave-action was from the west, and by the greater abundance of erratics on or below the beach than above it, that floating ice was at work. At the head of the fiord a blue clay dotted over with stones is now being formed, and the raised beach there consists of a similar material. Both here and elsewhere this clay stimulates a boulder clay; but for reasons given it was believed to be a marine fiord-deposit, into which many stones have been dropped by floating ice. Deposits of true glacial age, in the form of mounds of gravel, were described, and shown to have yielded the material out of which parts of the raised beaches were formed. The glaciation of the fiord was attributed to floating ice, and was shown to have taken place before the formation of the raised beaches, at a time when the sea surrounded this part of Finmark, by way of the Varanger Fiord, the Tana Valley, and the Tana Fiord. In the discussion upon the two papers, the President congratulated the author on the admirable manner in which he had worked out the evidence produced from the Varanger Fiord, and on his being able to show so conclusively that the views put forward by Dr. Reusch were substantially correct. Sir Archibald Geikie referred to one or two difficulties in the interpretations adopted by the author, one of the most obvious being the striated pavement of quartzite below the boulder-bed. This difficulty, however, was not insuperable. With regard to the age of the Gaisa series, Sir Archibald Geikie remarked that he was inclined to adopt the view of Dr. Reusch, who compared this series with the sparagmite of Central and Southern Norway. He himself had seen the sparagmite *in situ*, and had been much struck with its general resemblance, both in scenery and in lithology, with the Torridonian rocks of north-west Scotland. It was, like those rocks older than the Cambrian system. Dr. J. W. Gregory pointed out that the previous failure to discover traces of glacial action in high northern latitudes in pre-Pleistocene times gave wide interest to Reusch's paper; and the corroboration of his views by Mr. Strahan was of great value. He thought the deposits of special interest, as similar conglomerates occupying identically the same stratigraphical position occur all round the Polar basin, and in places where their age can be proved. In Spitzbergen the occurrence of the conglomerates was discovered last summer, and they are there pre-Devonian. Evidence seems to show that the conglomerates are probably part of a circumpolar belt. Mr. Hudleston corroborated the author's statements as to the nature of the country and of the arenaceous quartzite system prevailing in Eastern Finmark. Beyond the region shown in his map, on the eastern side of the Tana Fiord, the Stauganes Fjeld rises rather steeply to heights probably reaching 3000 feet. This is a quartzite wilderness, almost as white as snow, having a strong external resemblance to the quartzite-mountains of the North-western Highlands; the system might thus include both Torridonian and basal Cambrian beds. The importance of the author's verification of Reusch's statements was very great. The late Dr. Croll had been desirous of obtaining evidences of glaciation in the several formations anterior to the great Ice Age. His failure to do so he attributed to the circumstance that the evidences of glaciation are to be found principally on land-surfaces, and that the transformation of a land-surface into a sea-bottom would in most cases obliterate all traces of glaciation. A striated bed-rock went much further in this direction than mere boulders and striated stones; and, as far as he (the speaker) knew, these occurrences on the Varanger Fiord were the only ones as yet established in the northern hemisphere, with some possible exceptions in the case of the Talchirs. For a grander exhibition of striated bed-rock they must look to the southern hemisphere: Prof. Edgeworth David had recently brought before the Society such evidence from Southern Australia, referred to the Permo-Carboniferous period.

Chemical Society, January 21.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read: Observations on the properties of some highly purified substances, by W. A. Shenstone. The author shows that oxygen is far more readily ozonised when moist than when dry; the conversion of ozone into oxygen is greatly retarded by the presence of moisture. Carefully purified and dried chlorine combines readily with mercury, but is not condensed by a silent electrical discharge.—The action of diastase on starch, by A. R. Ling and J. L. Baker. Starch, when hydrolysed by diastase; is converted into a series of maltodextrins of gradually decreasing molecular weight and rotatory power and of increasing cupric reducing power.—The solution density and cupric reducing power of dextrose, lævulose and invert-sugar, by H. T. Brown, G. H. Morris, and J. H. Millar.—Derivatives of maclurin, Part II., by A. G. Perkin. Although maclurin yields no definite acetyl-derivatives, a triacetyl-derivative of maclurin-azobenzene can be prepared; similarly the azobenzene of phloroglucin yields a monacetyl-derivative.—Halogen-substituted acidic thiocarbimides and their derivatives; a contribution to the chemistry of the thiohydantoins, by A. E. Dixon. By the action of primary or secondary amines on halogen-substituted thiocarbimides a number of substituted thiohydantoins have been prepared.—The amyl (secondary butyl-methyl) derivatives of glyceric, diacetylglyceric, and dibenzoylglyceric acids, active and inactive, by P. Frankland and T. S. Price. The authors have prepared a number of inactive and active amyl salts of substituted glyceric acids, and investigated the effect of temperature on their rotatory powers and the relations between the rotations.—The refraction constants of crystalline salts, by A. E. Tutton.—The refraction constants of crystalline salts: a correction, by W. J. Pope.—On the wide dissemination of some of the rarer elements and the mode of their association in common ores and minerals, by W. N. Hartley and H. Ramage. Out of 168 ores and minerals examined, 68 contained gallium, 30 contained indium, 17 contained thallium, and 70 probably contained rubidium; conclusions are drawn respecting the formation of beds and lodes of ore, and relations are found to exist between the periodic classification and the distribution of the elements.

Zoological Society, February 2.—Prof. George B. Howes in the chair.—Mr. Sclater exhibited a collection of bird-skins that had been formed by Mr. W. A. Churchill, H.B.M. Consul at Mozambique, during various shooting-excursions along the shores within twenty miles of the island of Mozambique.—Mr.

R. E. Holding, on behalf of Sir Douglas Brooke, Bart., exhibited a head and two pair of shed horns of a fallow deer. The latter showed curious deformities in consequence of disease of the frontal bone.—Mr. G. E. H. Barrett-Hamilton gave a short general account of his expedition to the Fur-Seal Islands of the North Pacific during the summer of 1896, in company with Prof. D'Arcy Thompson. This journey had been undertaken on behalf of the Foreign and Colonial Offices, with a view to the investigation of the natural history of the northern fur-seal (*Otaria ursina*), with special reference to certain disputed points which had a distinct bearing on the industry connected with the skins of the animal. A detailed report of Mr. Barrett-Hamilton's investigations would be issued as a Parliamentary Blue Book.—Mr. G. A. Boulenger, F.R.S., read a paper entitled "A Catalogue of the Reptiles and Batrachians of Celebes, with special reference to the collections made by Drs. P. and F. Sarasin in 1893-1896." This memoir gave a complete list (with descriptions) of all the reptiles and batrachians, with the exception of the marine species, known to occur in the Celebes. The number of species of reptiles enumerated was 83, and of batrachians 21.—Mr. Martin Jacoby contributed to our knowledge of the African fauna by describing 43 species of Phytophagous Coleoptera, 37 of which were new, based on specimens contained in collections sent home to him from Natal and Mashonaland by Mr. Guy A. K. Marshall, and from Madagascar by M. Alluand, of Paris.

CAMBRIDGE.

Philosophical Society, January 25.—Mr. F. Darwin, President, in the chair.—Some results obtained by staining the brain with the chrome-silver method (illustrated by photomicrographs), by Dr. A. Hill. Dr. Hill showed a granule of the olfactory bulb with a looped axis-cylinder, and also certain forms of granule of the cerebellum not hitherto described. He also exhibited sections and photographs showing the variations in the form of the "thorns" on the dendrites of nerve-cells, which can be produced by varying the hardening process: (1) The thorns may be absent; (2) they may be long or short; (3) they may have the typical form of a minute rod with a dot at the end, or the dots may be divided and lie on the course of the rod; (4) they may be replaced by long filaments.—A possible explanation of the quinqueloculine arrangement of the chambers of the microspheric forms of triloculine and biloculine shells of the miliolidæ (foraminifera), by Mr. J. J. Lister. It was suggested that the quinqueloculine mode of growth in the young microspheric forms of the miliolidæ may be ancestral and archaic.—On the theory of osmotic forces, by Mr. J. Larmor (will be printed in full).

MANCHESTER.

Literary and Philosophical Society, January 26.—Prof. H. B. Dixon, F.R.S., in the chair.—On a convection scope and calorimeter, by A. R. Bennett. Mr. Bennett described how he had devised a small and exceedingly sensitive motor which begins to revolve the moment it is exposed to daylight in the open air, whether the sun is shining or not, and which will also work all night in clear weather. The delicacy of the motor is such that it is affected by the radiant heat of moonlight. The motive power is due to convection currents caused by the radiant heat of daylight striking through a glass shade with which the instrument is covered; the glass is not heated, but the metal surfaces of the instrument are, and air is consequently expanded on the motor surfaces and condensed on the glass, the resulting difference of temperature setting up a convection current which does not cease so long as the instrument is exposed to the radiant heat due to visible rays. Descriptions were given of modifications by which surplus heat is automatically stored during the day and employed to drive the instrument at night. During the months of May, June, and July last, such a storage instrument continued in motion without stopping day or night; and in fine climates, like Egypt, much longer periods of continuous movement could undoubtedly be secured. The speed of the instrument is affected by barometrical pressure and hygroscopic conditions. It is capable of marking the dew-point, and works well even when its glass shade is completely coated with ice or half buried in snow. Mr. Bennett has succeeded in adapting the instrument to act as a calorimeter by first cooling the whole of the instrument to a given temperature, when rotation ceases, and then suspending pieces of heated metal inside. In this way the specific heats of substances can be accurately compared, since the number of rotations caused is in direct proportion to the amount of introduced heat. The instrument can also be used to measure the comparative heat-retaining power of textile fabrics, boiler compositions, &c., and the relative heat conductivities of thin threads and wires. Mr. Bennett has also instituted a series of experiments, as yet incomplete, into the comparative sensitiveness to convection effects of various gases, which promise interesting results, since the differences already noted are unexpectedly great, and, moreover, do not bear any direct relation to the densities or other known physical properties of the gases tried.

PARIS.

Academy of Sciences, February 1.—M. A. Chatin in the chair.—The election of M. Filhol in the Section of Anatomy and Zoology, in the place of M. Sappey, was approved by the President of the Republic.—On a mode of inversion of multiple integrals, by M. Paul Appell.—On the integration of certain differential equations by series, by M. Émile Picard.—Further details on an apparatus for producing acetylene, by M. H. L. Lechappe.—On a scheme of night signalling on railways by phosphorescence, by M. A. Boullerot.—On a new instrument designed to show the upward or downward movement in balloons, by M. Aug. Coret.—Distance of the solar system, by M. E. Roger. A discussion of the two laws enounced by M. Delauney. It is stated that the first law may be attributed to chance agreement, and that the second is a particular case of a more general law.—On the quadratic integrals of the equations of dynamics, by M. P. Painlevé.—On the laws of interest, by M. Enrico de Montel.—Generalisation of the formulæ of electromagnetism, by M. Vaschy.—On the molecular conductivity of salts in dilute solution, by M. P. Joubin.—On the radio-photography of the soft parts of man and animals, by MM. Remy and Contremoulin. Silver chromate is deposited by a preliminary chemical treatment on the surface, and in the tissues of the muscles. In this way photographs can be obtained by means of the Röntgen rays in which not only the muscles, but even the muscular bundles are clearly visible.—Structural isomerism and rotatory power, by MM. Ph. A. Guye and J. Guerchgorine. The results of an experimental study of the rotatory power of the amyl isovalerates, derived from the three isomeric valeric acids; of the propyl and butyl valerates, obtained from the active valeric acid; and of the propyl and butyl caproates, prepared with caproic acid obtained synthetically by the decomposition of active amyl-malonic acid. It is found that in all cases the normal propyl group behaves as though it were heavier than the isopropyl group, but that the isobutyl group appears to be heavier than the normal butyl group, whilst the latter, again, is heavier than the secondary butyl group.—Constitution of the combinations of antipyrin with phenols, by M. G. Patein. It is shown that monomethylphenyl-pyrazolone does not combine with phenols, and that the phenol is probably joined, in the case of the combination with antipyrin, to one of the nitrogen atoms.—On the estimation of lipase, the saponifying ferment in the blood, by MM. Hanriot and L. Camus. The estimation was carried out by measuring the amount of sodium butyrate formed by the saponification of butyrin during a fixed time. The activity of lipase prepared from the blood serum of the horse was shown by preliminary experiments to be unchanged after nearly two months' preservation; the temperature, however, exerts a considerable influence upon the results, and has to be kept constant during the determination.—On a new method of preparing anatomical specimens, by M. N. Melnikoff-Rasvédenkoff. The specimen is treated successively with a solution of formaline, alcohol (60 to 80 per cent.), and a solution made up of water (100), glycerine (20), and potassium acetate (15).—Separation of glycerine in wine by means of a current of steam, by MM. F. Bordas and Sig. de Raczkowski. Test analyses are given showing the accuracy of the method.—Contribution to the study of the action of zinc upon red wines, by M. L. A. Levat. The amount of zinc taken up by the wine is sufficient to make the latter poisonous, and this metal should not be used for taps, or for containing vessels of any kind in which wines are stored.—Structure and mechanism of the bulb in the Mollusca, by M. Alexandre Amandrut.—On a method of mounting rotifers, by M. Nicolas de Zograf. The rotifers are narcotised with a solution of cocaine hydrochloride, and then treated with osmic acid. This is removed and replaced by weak crude wood vinegar, then the animals washed with water and dried by alcohol. The rotifers fixed in this way do not contract their abdominal appendages, cilia, or tentacles.—The *castoreum* of the roach, by

M. Jules Gal.—New researches on the *Amylotrogus*, by M. E. Roze.—The forms of the parasite of the black rot from autumn to spring, by M. A. Prunet.—On the effects of oil at sea, by M. Baretge. An account of the successful use of oil in breaking up large waves during a storm. It was found that for the oil to produce its maximum effect, the vessel must have a certain speed depending upon the state of the sea. For the case described a speed of eight knots was found to be the most favourable.—Relations between the masses of the solar system, by M. Delauney.—Note on some questions in celestial mechanics, by M. J. Mortij.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 11.

ROYAL SOCIETY, at 4.30.—The Oviposition of *Nautilus macromphalus*: Dr. A. Willey.—Report to the Committee of the Royal Society appointed to investigate the Structure of a Coral Reef by Boring: Prof. Sollas, F.R.S.—The Artificial Insemination of Mammalia and subsequent possible Fertilisation or Impregnation of their Ova: W. Heape.—On the Regeneration of Nerves: Dr. R. Kennedy.

ROYAL INSTITUTION, at 3.—Problems of Arctic Geology: Dr. J. W. Gregory.

SOCIETY OF ARTS (Imperial Institute), at 4.30.—The Progress of Science Teaching in India: Prof. Jagadis Chundra Bose.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

MATHEMATICAL SOCIETY, at 8.—A Theorem in Non-Euclidean Geometry: F. S. Macaulay.—On some General Theorems relating to Conics analogous to Simson's-Line Theorem: H. M. Taylor.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Electric Interlocking the Block and Mechanical Signals on Railways: F. T. Hollins.

CAMERA CLUB, at 8.15.—The Making and Exhibiting of Living Photographs: Birt Acres.

FRIDAY, FEBRUARY 12.

ROYAL INSTITUTION, at 9.—Recent Advances in Seismology: Prof. John Milne, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 3.—Annual Meeting.

PHYSICAL SOCIETY, at 5.—Annual Meeting.—Note on the Use of very small Mirrors with Paraffin Lamp and Scale: Dr. H. H. Hoffert.—On the Thermoelectric Properties of Liquid Metals: W. Beckett Binnie.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Cooling Reservoirs for Condensing Engines: Harold W. Barker.

MALACOLOGICAL SOCIETY, at 8.—Annual Meeting.

SATURDAY, FEBRUARY 13.

ROYAL INSTITUTION, at 3.—The Growth of the Mediterranean Route to the East: W. F. Lord.

ROYAL BOTANIC SOCIETY, at 4.

MONDAY, FEBRUARY 15.

SOCIETY OF ARTS, at 8.—The Industrial Uses of Cellulose: C. F. Cross.

IMPERIAL INSTITUTE, at 8.30.—Sixty Years of Submarine Telegraphy: Prof. W. E. Ayrton, F.R.S.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Adjourned Discussion on Mr. W. J. Dibdin's Paper on the Character of the London Water Supply.

VICTORIA INSTITUTE, at 4.30.—Are Acquired Characters Inherited?

TUESDAY, FEBRUARY 16.

ROYAL INSTITUTION, at 3.—Animal Electricity: Prof. A. D. Waller, F.R.S.

SOCIETY OF ARTS, at 8.—The Progress of Canada during the past Sixty Years of her Majesty's Reign: Joseph G. Colmer, C.M.G

ZOOLOGICAL SOCIETY, at 8.30.—On Echidnocephalus, a Halosauroid Fish from the Upper Cretaceous Formation of Westphalia: A. Smith Woodward.—On a Specimen of Acanthocybium solandi from the Arabian Sea: G. A. Boulenger, F.R.S.—Remarks on the Existing Forms of Giraffe: W. E. de Winton.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: Cold Storage at the London and India Docks: H. F. Donaldson.

ROYAL STATISTICAL SOCIETY, at 5.30.—English Vaccination and Small-pox Statistics; with special reference to the Report of the Royal Commission, and to recent Small-pox Epidemics: Noel A. Humphreys.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.

WEDNESDAY, FEBRUARY 17.

SOCIETY OF ARTS, at 8.—Light Railways: Everard R. Calthrop.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Report on the Phenological Observations for 1896: Edward Mawley, President.—Results of Observations on Haze and Transparency near Haslemere, Surrey: Hon. F. A. Rollo Russell.

ROYAL MICROSCOPICAL SOCIETY, at 8.—On a Simple Method of Microphotography: G. M. Giles.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, FEBRUARY 18.

ROYAL SOCIETY, at 4.30.—The following Papers will *probably* be read:—On the Iron Lines present in the Hottest Stars (Preliminary Note): J. N. Lockyer, F.R.S.—On the Significance of Bravais' Formulæ for Regression, &c., in the case of Skew Variation: G. U. Yule.—Mathematical Contributions to the Theory of Evolution. On a Form of Spurious Correlation which may arise when Indices are used in the Measurement of Organs: Prof. K. Pearson, F.R.S.—Note to the Memoir of Prof. Karl Pearson, F.R.S., on Spurious Correlation: F. Galton, F.R.S.

ROYAL INSTITUTION, at 3.—Problems of Arctic Geology: Dr. J. W. Gregory.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

LINNEAN SOCIETY, at 8.—On certain Points in the Anatomy and Morphology of the Nymphæaceæ: D. T. Gwynne Vaughan.—The Adhesive Discs of Ercilla spicata, Uog.: T. H. Burrage.

CHEMICAL SOCIETY, at 8.—The Oxidation of Sulphurous Acid by Potassium Permanganate: T. S. Dymond and F. Hughes.—Sodamide and some of its Substitution Derivatives; also Rubidamide: Dr. A. W. Titherley.

CAMERA CLUB, at 8.15. Practical Use of X-Rays: Sydney Rowland.

FRIDAY, FEBRUARY 19.

ROYAL INSTITUTION, at 9.—The Approaching Return of the Great Swarm of November Meteors: Dr. G. Johnstone Stoney, F.R.S.

GEOLOGICAL SOCIETY, at 3.—Annual Meeting.

EPIDEMIOLOGICAL SOCIETY, at 8.

SATURDAY, FEBRUARY 20.

ROYAL INSTITUTION, at 3.—Growth of the Mediterranean Route to the East: W. F. Lord.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Is Natural Selection the Creator of Species?: D. Graham (Digby).—Everybody's Guide to Photography: "Operator" (Saxon).—Everybody's English Song-Book: "Basso" (Saxon).—Star Atlas: Prof. W. Upton (Ginn).—Calendar, &c., of the Department of Science and Art, 1897 (Eyre).—Bacteria of the Sputa and Cryptogamic Flora of the Mouth: Dr. F. Vicentini, translated by Rev. E. J. Stutter and Prof. E. Saieghi (Baillière).—Les Succédanés du Chiffon en Papeterie: V. Urbain (Paris, Gauthier-Villars).—Projectiles de Campagne de Siège et de Place. Fusées: E. Vallier (Paris, Gauthier-Villars).—L'Éclairage: Éclairage aux Gaz, &c.: Prof. J. Lefèvre (Paris, Gauthier-Villars).—A Text-Book of Histology: A. Clarkson (Bristol, Wright) —Annales de L'Observatoire Météorologique du Mont Blanc, Tome ii. (Paris, Steinheil).—Bulletin of the Philosophical Society of Washington, Vol. xii. (Washington).

PAMPHLETS.—First Records of British Flowering Plants: W. A. Clarke (West).—Casa Grande Ruin: C. Mindeleff (Washington).—Some Analogies in the Lower Cretaceous of Europe and America: L. F. Ward (Washington).—Aboriginal Remains in Verde Valley, Arizona: C. Mindeleff (Washington).

SERIALS.—Scribner's Magazine, February (S. Low).—Journal of the Institution of Electrical Engineers, No. 125, Vol. xxv. (Spon).—Strand Magazine, February (Newnes).—Bulletin of the American Mathematical Society, January (New York, Macmillan).—Proceedings of the Royal Society of Edinburgh, Vol. xxi. No. 3, Pp. 161–248 (Edinburgh).—Physical Review, Part xxii. OUR MARKETABLE MARINE FISHES.

The Natural History of the Marketable Marine Fishes of the British Islands. By J. T. Cunningham, M.A. Pp. xvi + 368, 2 maps, and numerous cuts. (London: Macmillan and Co., Ltd., 1896.)

THE great Fisheries Exhibition held in London in 1883 gave a marked impulse to the study of our sea-fisheries, and drew the attention both of scientific men and of the more enlightened of the general public to the importance of the subject and to the necessity of endeavouring to "arrive at an accurate estimate of the causes which determine the movements and the variations in abundance of the animals which produce the harvest of the sea." The Marine Biological Association of the United Kingdom, founded shortly afterwards (1884), has done much during the last decade to trace out the life-histories and habits of many of our food fishes; the scientific investigations of the Fishery Board for Scotland, and the researches carried on at Prof. M'Intosh's marine laboratory at St. Andrews, have done still more; and other public bodies and individuals round the coast have assisted in a less degree in collecting the information which has made possible such a book as the one before us.

Mr. Cunningham, who has been employed since 1887 as "naturalist" by the Marine Biological Association at their Plymouth laboratory, produced some years ago a finely illustrated monograph on the common sole; and now, under the direction of the Council of the same body, he has prepared this work on our marketable marine fishes, with the view of bringing before the general reader, in a connected narrative form, the gist of the information contained in the numerous technical memoirs which have appeared from various laboratories during the last few years. It is generally agreed that the fisherman might with advantage know a great deal more than he does about the objects of his search, but there are some of us who think that at the present juncture what is most required is an educated public opinion. It is probably as important for the future of fisheries investigation and improvement, and of just legislation in regard to the fisheries, that the general public should have opportunities of learning and realising the truth in regard to the habits and life-histories of food fishes, and the inter-relations of animals in the sea, as it is that the fisherman himself should be instructed in such matters. In addition to public lectures, by competent authorities, and the establishment of technical fisheries museums, the publication of books such as the present one, and the larger work which we understand Prof. M'Intosh is preparing, should not only prove useful to those who are, *or ought to be*, interested in fishery matters, either for profit or from the legislative point of view, but will serve as a guide in forming opinions on those fishery questions which have now to be discussed and decided by County Councils and Committees for Technical Instruction, by Conservancy and other Boards, in Law Courts and in the House of Commons.

The Marine Biological Association has been aided by large grants from Her Majesty's Treasury on the understanding that special attention should be directed to the investigation of sea-fish and sea-fisheries, and the present volume will naturally be taken as stating the general conclusions arrived at by Mr. Cunningham, the member of the staff especially charged with the fishery investigation, both from his own work and the consideration of the work of other naturalists at various points around the British coast. Under these circumstances it is to be regretted that Mr. Cunningham has not made more use than appears in his book of the statistics and other local investigations of the Lancashire Sea-Fisheries Committee. Most of his statements are taken from observations made at Grimsby and at Plymouth; but the Irish Sea forms an English fishing area second only in importance to the North Sea, and from which examples might well have been quoted. Even in the appendix, dealing specially with the fishing grounds of the British Islands, the Irish Sea is conspicuous by its absence, and no reference is made either to the "inshore" or "offshore" Lancashire trawling-grounds.

Prof. Ray Lankester, as President of the Marine Biological Association, introduces the book with a preface in which he states as his opinion that "nothing short of a physical and biological survey of the North Sea and of the area within the hundred-fathom line on our southern and western coasts can yield the information as to the movements of marine food fishes and the distribution of fishing grounds which is needful if we are to deal intelligently with our sea-fisheries." With that opinion we heartily concur. It is practically what the present writer urged in a presidential address to Section D of the British Association in 1895, when he said . . . "it would be a very wise action, in the interests of the national fisheries, for the Government to fit out an expedition, in charge of two or three zoologists and fisheries experts, to spend a couple of years in exploring more systematically than has yet been done, or can otherwise be done, our British coasts from the Laminarian zone down to the deep mud." I may now add that in such a scheme I should *not* omit the Irish Sea—a natural sea-fisheries district, with breeding grounds and feeding grounds, estuaries, and open sea, great expanses of shallow banks, and coasts where you can go "from the Laminarian zone down to the deep mud," at eighty fathoms, in about twelve miles.

Mr. Cunningham's book is divided into two parts. Part I. is general, and deals with the history of fisheries investigations, the general characters and distribution of marine fishes, their methods of reproduction and their development, their growth, migration, food, and habits; and finally a discussion of practical methods for increasing the supply of fish. Part II. is special, and takes up the history of particular fishes arranged according to their families, from the "Herrings" to the "Suckers." Part I. is interesting reading; Part II. is more the work of reference in which to look up the details of certain species. The interesting story of Sars' discovery in 1864 and 1865, of the floating eggs of the cod, haddock, and mackerel in Norway, and of M'Intosh's important work in Scotland, of the work of the Kiel Commission in Germany, and of the Fishery Board for Scotland, are all given in

the first chapter. But in this historical section the reference to the Sea Fisheries Committees round the coasts of England and Wales is too brief, and their work is practically ignored.

Even though the book is written not for the specialist, but for the general public, we think too obvious and elaborate an attempt has been made to avoid technical terms. Some of the "English" substitutes are no improvement from any one's point of view, and are wanting in precision and sense—for example, we find mammals referred to as "the tribe of beasts," and, curiously enough, after using the term "pectoral fin" at the beginning, the author discards it during the remainder of the book in favour of "breast fin." Then again, when such a technical term as "micropyle" is used, there seems no reason for calling the oviduct "egg-tube"; while to label an unfortunate little blenny "the Gattorugine" is quite as bad as to use its proper scientific name. We should have been glad to have seen the scientific names of the species associated with the English names throughout the book, and especially under the useful outline figures. It is easy to pick up the scientific names, and the sooner those of the public who are concerned with fishery matters do so the better. On p. 40, when defining species, genera, and families, the names of a few well-known genera, such as *Gadus*, and *Clupea*, and their more important species, might have been introduced with advantage.

Although we quite agree with Mr. Cunningham's remark, that at present it must be held that artificial propagation of sea-fish is in its experimental stage, still we think that throughout that discussion on practical methods he does not, in stating the case for hatching, allow sufficiently for the fact that the embryos are protected in the hatchery during a period of their existence when, if at large, they are liable to become the prey of nearly everything in the sea that has a mouth.

There are some misprints in the book, which should have been corrected in proof: *e.g.* on p. 87, *Lota vulgaris* is called the turbot; Prof. M'Intosh's name is misspelled throughout the book, as is also *Hydrallmania*, which should have only one "n."

There are some other points one might take exception to, but we have criticised enough; and most of the blemishes we have alluded to above are of minor importance, and leave the book a really valuable work and a record of much research and long-continued industry on the part of the author. We hope that the book will prove useful in the hands of superintendents of fishery districts and members of our Sea Fisheries Committees. The numerous illustrations are most of them excellent, and the general "get-up" is all that could be desired.

W. A. HERDMAN.

THE LIFE OF JAMES CROLL.

Autobiographical Sketch of James Croll, with Memoir of his Life and Work. By J. C. Irons. Pp. 553. (London: Stanford, 1896.)

THE life of James Croll is very remarkable. That a mason's son, who in youth laboured on the few acres of his father's homestead; who then, having a mind disposed to mechanics, became apprentice to a millwright; who, having served his four years' time, got employment at eight shillings a week, having sometimes to walk thirty or forty miles a day to his work, and to sleep in the barn; who, not becoming inured to such hardships, turned carpenter, and met with some measure of success, till disease in the elbow set in; who then, not having sufficient education for a clerkship, found employment in the tea trade, and was after a time helped by his employer to open a shop for his own profit—in which venture he might have succeeded, even in spite of reading "Edwards on the Will," had not the elbow caused a long and painful illness which ruined the business, and left him with an ossified joint; who then supported himself for a twelvemonth by making electrical instruments wherewith the neighbours might cure themselves of all the ills the flesh was heir to; who, when the demand for the panacea was exhausted, "after due consideration," set up a temperance hotel in a town, Blairgowrie, of 3500 inhabitants, with sixteen inns and public-houses there already, and far from any railway; who, after a year and a half of failure as innkeeper, took to canvassing for various insurance companies, where, as usual, everything went contrariwise with him—that a man, who thus spent nearly the first forty years of his life, should have become so successful a student of metaphysics as to write a work of decided merit on "The Philosophy of Theism," is perhaps not a matter of surprise, seeing that he was a Scotchman. But we may surely indulge our faculty of wonder when we learn that a London publisher was found ready to undertake the whole risk of publishing his work, by an unknown Scotch tradesman or agent, on the terms of half profits, and that the result justified the publisher's enterprise.

But at length, in 1859, these difficulties were overcome, and Croll obtained a situation as janitor at the Andersonian College, Glasgow. The salary was small, but he had ample time to read, and some excellent libraries to consult; and here he may be said to have begun his scientific career. After eight years he was appointed to the Geological Survey of Scotland, where he remained thirteen years. Through ill-health he then retired, expecting to have received a pension calculated on age as well as length of service; but in this he was disappointed. The Treasury refused to pay more than 75*l.* 16*s.* 8*d.* a year. The circumstances of the refusal, as set forth in the correspondence, render the transaction a lasting disgrace to the Treasury. Ten years later he died.

There is here a striking record of difficulties overcome. Yet these, the external difficulties, were the least with which Croll had to struggle. His head, always a bad servant to his mind, became, in 1865, so seriously affected, that never afterwards could he persist for any length of time in mental work, or concentrate his energy on a difficulty until it was overcome. If he attempted to do too much, not only did the pain become unbearable, but he was disabled for several days afterwards. How terribly this affliction influenced his life may be judged from the fact, mentioned in Croll's simple, modest way, that he had to take a by-path in the morning, lest conversing with a friend on the way should unfit him for his office work.

Even from this bare outline it may be judged that the

story of Croll's life, as all too shortly told by himself, and supplemented by Mr. Irons, is one of deep pathos.

Of his character, deeply impressed by the truths of religion, Calvinistic, conscientious to a degree, possessed of the most inflexible power over himself, not hesitating to subject himself to severe and long-continued physical suffering when he thought it his duty, full of generosity in assisting other inquirers after truth, we obtain many glimpses in the volume before us.

Of Croll's scientific work, which bears at once the impress of genius, metaphysically acute, and of imperfect knowledge, the result of unsystematic training in physics, it is more difficult to form a just estimate. It was so controversial, and dealt with matters on which the final judgment of science has not yet been passed. That which he regarded as his most important and most conclusive work in physics—his glacial theory—has been steadily losing ground among geologists and physicists alike, and now it finds difficulty in securing a champion to fight its battles. His work on ocean currents seems more likely to be permanent, for he did much to call attention to the paramount importance of winds in determining oceanic circulation, although he doubtless pushed the argument somewhat too far against Carpenter, the advocate of the temperature theory; yet the very imperfections of his work bear the strongest testimony to the inherent suggestive genius of the man. That one whose knowledge of elementary physical principles was so confused as appears from some of the correspondence, *e.g.* that on pp. 452–458, should have been able to sway contemporary scientific opinion on physical subjects was marvellous, and was due, not only to the extraordinary suggestiveness of his mind, but also to his metaphysical power. By long-continued meditation, the different parts of his theory became in his mind so closely connected together, analogies became so clearly perceived, so unconsciously magnified, that difficulties faded into the background, or, even in his fertile mind, were made to yield new reasons for his conclusions. Yet, through all, the transparent sincerity of the author, and his evident devotion to truth were as clear as his absolute conviction of the necessity of his own conclusions; and thus, as well as by his remarkable power of logical exposition, he imbued the reader with his own confidence, and this the more readily in the case of the glacial theory, because the grandeur and simplicity of the explanation, if it did not afford some presumption of its truth, at least created a prejudice in its favour.

But though Croll's position will doubtless be determined by his work in physics, he would himself have chosen to be judged by his metaphysical writings. If we may judge from the summaries in the work before us, as well as the correspondence from Principal Cairns and others, these works were of striking, though by no means of transcendent, merit.

The book is well printed and got-up. To one who did not know Croll personally, it seems that some of the correspondence might have been omitted with advantage. It is, however, an ungrateful task to criticise what has been a labour of love. The last words of the preface are: "It may be added that the entire proceeds of the sale will be devoted to Dr. Croll's widow."

E. P. C.

ELEMENTARY METEOROLOGY.

Elementary Meteorology for High Schools and Colleges. By Frank Waldo, Ph.D., late Junior Professor in the U.S. Signal Service. Pp. 4 + 373. (New York: Cincinnati, Chicago American Book Co., 1896.)

IN writing an elementary treatise on meteorology, there are two very evident errors which an author may commit. There is the danger of producing a book which is reduced to such simplicity that it becomes wearisome or even needless, because it contains many facts which are either of ordinary experience or have been learnt from other branches of elementary physics. And on the other hand, there is the difficulty, common to all elementary works, of knowing where to stop. To the adept, many facts and deductions, which appear perfectly simple and worthy of attention, are stumbling-blocks to the beginner and become sources of annoyance to the reader. In looking through this book one learns that there are other difficulties which need to be avoided, and though Dr. Waldo has to some extent avoided the big pitfalls by steering clear of childish repetition on the one hand, and injudicious overloading on the other, he has not been so successful in recognising the necessity of accuracy of expression and clearness of explanation. One might, too, take a preliminary objection to the choice of the readers to whom this book is addressed. Dr. Waldo admits in his very first paragraph that the "science is as yet but partially developed, and much that is at present accepted as fact will be modified by future investigations.' The question naturally arises, is it desirable to place before students explanations that are admittedly imperfect, and to devote the time that might be well spent in accurate training to the acquisition of an amount of ill-digested information, that does not in all cases even satisfy those with whom the information has originated? Of course, no blame rests with Dr. Waldo on this score. If those who are responsible for education in America are determined to press some acquaintance with meteorology in its present condition on their pupils, it is clearly the duty of experts to supply the best text-books in their power, so that the least possible injury be effected. Of Dr. Waldo's capacity and intimate acquaintance with the subject of which he treats, there is no question. But he does not always exhibit sufficient care to place his facts in the clearest possible light, so as to be of the greatest possible assistance to the student. As an illustration of this carelessness, we may take the sentence on page 30, beginning, "The heat received by the water surface warms it but slightly." This expression, as it stands, would mean that the surface of the water is but slightly warmed, and the explanation that follows would be incorrect; but what is really meant is that the whole mass of water is but slightly warmed by the sun's rays. Such looseness of expression must be very confusing to a student. Take another instance. It is stated (p. 21), "Our earth, in its revolution round the sun, intercepts less than one-half of a millionth of the whole amount of heat given off by the sun." Why are the words "in its revolution round the sun" introduced? These words obscure the real point at issue, which is, or should be, the comparison of the area of the sphere whose radius is the sun's distance from the earth, with the space the earth occupies in that

sphere. In this sense, the amount of heat intercepted by the earth is so much less than that mentioned as to make the statement misleading. Such blemishes are perhaps slight, and might well be passed over where so much of the work is excellent and well arranged. But a graver charge, and one that will surprise many who take up the book, is the neglect to place Boyle's law in a prominent position. One might go so far as to say that Boyle's law is not even mentioned. It does not occur in the index, and we have not found any reference to it in the text, so that it must be very obscurely expressed; and yet it seems imperative, that to such a fundamental principle great clearness and prominence should be given. We think, too, that the chapter on "atmospheric optics" might well have been omitted. There is nothing peculiar about "atmospheric optics," and if one wanted to know the theory of the rainbow, one would necessarily go to a book on optics, and we should imagine that in the "high schools and colleges" in America, students are taught their optics more thoroughly than is suggested by the sketchy manner in which the subject is here treated.

The most satisfactory chapters of the book are those which describe the winds and the circulation of the atmosphere. The author has closely followed Prof. Ferrel in his general explanation, and his intimate knowledge of the work of this physicist has enabled him to give much valuable information in a succinct and accurate form. Unfortunately, it is precisely in this section of meteorology that some of the views now held are most likely to meet with modification, but the chapters are valuable as presenting in a popular form the present condition of our knowledge. Another special and valuable feature in the book is the collection of results that have been derived from meteorological observations. These results are exhibited both in tabular and graphical form, and always clearly. Whatever may be thought of the value of many of the meteorological observations so persistently and energetically collected, there can be no doubt but through their means many useful facts have been learnt, which it is desirable to make known in the pleasantest manner possible. These results may end only in the knowledge of the climate of the district in which the observations have been made; they may not touch the general principles underlying the science of meteorology understood in its widest sense, but such results have a practical value in many arts and sciences, and it is a praiseworthy task to spread abroad a knowledge of the facts that have been collected, and likewise a grateful task to acknowledge the efforts of those who, like Dr. Waldo, have laboured on behalf of the service of meteorology.

OUR BOOK SHELF.

The Mechanics of Pumping Machinery. By Dr. Julius Weisbach and Prof. Gustav Herrmann. Translated from the second German edition by Karl P. Dahlstrom. Pp. 298. (London: Macmillan and Co., 1897.)

PUMPING operations occupy an important place in engineering works, for they are required for keeping out the water from foundations during construction, for raising water from deep wells, for the disposal of sewage, for the efficient drainage of low-lying lands, and for providing water under pressure for working hydraulic machinery. Accordingly, books explaining the principles of the various types of pumps, and affording information as to their relative efficiency, are valuable to engineers and contractors who are obliged to have recourse to pumping in their works. This book appears to be intended primarily for the instruction of students attending advanced courses on the mechanics of machinery; but the descriptions and clear illustrations of the different forms of pumps, should prove useful to those practically engaged in the raising of water. The first chapter relates to the early forms of water elevators, such as the balanced pole with a bucket hung from one end and counterpoise at the other, known as the *picottah* in Bengal and the *shadouf* in Egypt, flash wheels, scoop wheels, chain pumps, and the archimedean and other water screws; and the efficiencies of the wheels, chain pumps, and screws, are calculated. The three following chapters are devoted to the elementary action, the theory, and the various types of reciprocating pumps, the last subject extending over a hundred pages, or one-third of the book. Reciprocating pumps may be divided into two classes, namely, those having hollow valved pistons, or bucket pumps, and those having solid pistons, or plunger pumps; and they comprise both lift pumps and force pumps, generally combining suction as well, and embrace the most common forms of machines for raising water, and also fire-engine and water-pressure pumps. The fifth chapter describes different forms of rotary pumps, of which the centrifugal pump is the most familiar example, and furnishes calculations with regard to the form, velocity, and efficiency of these types of pumps. In the sixth and final chapter, the principles of the hydraulic ram, ejectors and injectors, spiral pumps, compressed-air pumps, the pulsometer, and syphons are explained with the aid of diagrams. The excellent woodcuts, indeed, 197 in number, dispersed throughout the text, elucidate the descriptions very efficiently. A table of contents at the head of each chapter would have been valuable for guidance, especially when a single chapter occupies one-third of the book, and also a list of the woodcuts, and headings to the principal illustrations; whilst an index of barely more than a page, does not afford adequate opportunities of reference. The translation has been so well performed, that the only reminders of the foreign origin of the book are the metric measures, after which have been added their English equivalents in brackets; but in a book drawn up expressly for English readers, the calculations, as well as the results, should have been converted into English measures, to which the most prominent place should have been assigned, even if it was considered advisable to retain the foreign measures. Pumping machinery has so long formed a speciality of several English manufacturers, that English authors should have rendered it unnecessary to resort to Germany for an exposition of the mechanics of pumping machinery. Germans, however, have been long renowned for the thoroughness of their scientific investigations, and Mr. Dahlstrom, of Lehigh University, has performed a valuable service in putting this book within the reach of American and British engineers and students.

Geography of Africa. By Edward Heawood, M.A. Pp. viii + 262. (London: Macmillan and Co., Ltd., 1896.)

THE publication of this little text-book in Macmillan's Geographical Series will be welcomed by all who are interested in geographical education, or who desire a handy and trustworthy compendium on Africa. Books made up mainly of tables of chief towns, lengths of rivers, and other statistical information, are, we hope and believe, on the decline, and rightly so; for they represent the worst methods of teaching geography. Throughout Mr. Heawood's volume, the principles kept in view are: "In the first place, the rule laid down by Dr. Mill in the 'General Geography' of this series, of proceeding from the general to the particular, has been adhered to; and in the second, a clear understanding of the broad physical features of each region described has been

taken as the necessary basis on which to build up the complete picture of such region as the sphere of human activity." A book constructed on these lines claims attention at the outset; and when, as is the case with the volume before us, the pages give evidence that the author is thoroughly familiar with all the geographical facts pertaining to the region with which he deals, we have the factors which combine to make a work useful as an educational instrument, valuable for reference, and interesting to geographical readers. It is, indeed, not too much to say that no book now in existence contains within such a small compass so much accurate information on the African continent as is given in Mr. Heawood's little volume. The book should be widely used in schools, and for this purpose the summary of the geography of Africa will be found very serviceable. To every one who wishes to possess a concise statement of the physical features, native inhabitants, history, and political development of Africa, the volume can be confidently recommended.

Crags and Craters: Rambles in the Island of Réunion. By W. D. Oliver, M.A. With illustrations and a map. Pp. xiv + 213. (London: Longmans, Green, and Co., 1896.)

IF we were going to Réunion (Bourbon), or had lately come back from it, we should be very glad to fall in with such a book as this. It gives an account of the experiences of an energetic man who spent six months on the island, and went about wherever curiosity led him. There is a good map and several photographs. The only illustration that is not a photograph is wretchedly bad. Our author writes easily and clearly, and has evidently taken pains to collect plenty of detailed information. Here the reader finds geography, history, statistics, scenery, manners and customs of the people—almost everything that can be desired, except natural history. What a pity that Mr. Oliver did not inquire beforehand what the naturalist wants to know about Réunion! Prof. Newton, of Cambridge, would have put him in the way of doing some really good work. A little fresh information about the extinct, or nearly extinct, birds, and the gigantic land-tortoises (if there are any in Réunion) would have greatly enriched the book. In spite of this deficiency, "Crags and Craters" is a valuable contribution. The schoolmaster in search of graphic details about the islands of the Indian Ocean would find much good stuff here. L. C. M.

Everybody's Guide to Photography. By "Operator." Pp. 162. (London: Saxon and Co.)

AMATEUR photographers are now so very numerous, that this book should find a large number of readers. There are hints on the choice of a photographic outfit, and simple directions on all the operations concerned in the production of good negatives and prints. Instructions are also given how to make enlargements and lantern slides, and on the use of orthochromatic plates, the production of stereoscopic photographs, flash-light photography, and Röntgen ray pictures.

Is Natural Selection the Creator of Species? By Duncan Graham. Pp. xviii + 303. (London: Digby, Long, and Co.)

ACCORDING to the author of this book, evolution by natural selection is a snare and a delusion. Wherefore, he comes forward to sweep away the whole fabric of evolution, and to show "that the condition of the earth and its inhabitants cannot be explained by the action of physical forces, independent of support and direction from an intelligent power." His qualifications for this task may be judged from the avowal that, although he has studied the nature and habits of animals and plants for many years, he has never discovered evidence that conclusively indicated evolution.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Force of a Ton.

THE hydraulic forging presses at the Armstrong works, which I had the privilege of visiting a short time ago, bore the inscriptions—2000 tons—5000 tons; meaning thereby the thrust exerted by the ram; and Dr. Lodge's opinion that the word *weight* should be supplied was rejected by the engineers, as the addition of the word *weight* would imply that the presses *weighed* 2000 or 5000 tons.

It is quietly assumed by Dr. Lodge and his followers that the word *weight* is never used except to denote the force with which a body is attracted by the Earth; as if we should never translate *weight* by *pondus*, *un poids*, *gewicht*, but always by *grave*, *un grave*, *schwere*; as in Galileo's memoir "De motu gravium naturaliter accelerato." To support this assumption the Act of Parliament on *Weights and Measures* is always quoted in a garbled form, with a view of making out that the standard Pound Weight is really not the lump of platinum specified in the Act, but the pressure on the bottom of the box in which it is preserved; probably with the mental reservation of the Mikado, "this is the careless way in which the Act is drafted; we will have it altered next time."

Thus the weight of the standard pound weight should, in Dr. Lodge's language, be given as 32·1912 poundals, when at rest in the box at Westminster, and when it is high-water at London Bridge, but changing suddenly to about 32·2382 poundals when tossed in the air. What the thrust of 5000 tons would become when expressed in poundals, funals, or even tonals, it is fearful to contemplate, as well as the pressure of the water in the press or modern steam pressures in poundals on the square foot.

If this controversial question is studied historically, it will be found that Prof. Perry is quite right in maintaining that the quantity denoted by m in Dynamics, and called the *mass*, is measured in units of *inertia*; the unit of inertia being that quantity of matter which receives unit acceleration from the unit force.

In all continental treatises, and in our own engineering works, the quantity w/g is replaced by the letter m and called the *mass*; this defines the unit mass as that quantity of matter which will receive the unit of acceleration from the gravitation unit of force.

Dr. Lodge changes to the absolute unit of force, and now replaces m by w; so that if the mass of a body is m pounds, it must weigh m lb.; and if moving with velocity v *f/s*, its kinetic energy is $mv^2/2$ foot-poundals, or $mv^2/2g$ foot-pounds; we have now come back to the engineer's measurement, except that his w has, for some mysterious reason, become m, and a different m to his w/g.

I agree with Mr. C. S. Jackson, to a certain extent in opposition to Prof. Perry, in the opinion that the substitution of m for w/g had better be abandoned; or, as a compromise, the letter m may replace w; because a body whose mass is m or w pounds must weigh m or w lb. in the balance; in ordinary language, its weight is m or w lb.

It is the old mediæval discussion of Nominalism and Realism over again; does the thing alter when we call it by a different name? If a steamer loads 1000 tons of coal, are we no longer to say that this coal weighs 1000 tons; or that 1000 tons weight has been placed on board? Are we to be compelled to say that the coal masses 1000 tons; and that it is 1000 tons mass?

In a redetermination of the volume of the gallon, Mr. H. J. Chaney has found that a cubic inch of distilled water, freed from air, and weighed against brass weights in air, when the temperature is 62° F. and the height of the barometer is 30 inches, is equilibrated by 252·286 grains; and this makes the volume of the gallon 277·463 cubic inches, according to the Act of Parliament (*Phil. Trans.*, 1892). Mr. Chaney calls this 252·286 grains the *mass* of a cubic inch of water; but if the same weighing is carried out in *vacuo*, according to another clause of the Act, an extra 0·266 grain must be added to maintain equilibrium; what are we now to call this 252·552 grains, with respect to a cubic inch of water?

The object of writing m for w/g, or of changing to the absolute unit of force and writing m for w, is merely to get rid of g in the dynamical equations, which concern the problems which alone are capable of direct human measurement.

But this quantity g, so treacherous as Dr. Lodge can testify, should always be kept carefully in sight; any attempt to get rid of it merely causes it to reappear elsewhere in an unexpected place (*expelles furca*, &c.).

The engineer can be left to take care of himself, and does not require to be instructed in an art with which he is perfectly familiar. Considering that he has been compelled to create for himself, without professorial assistance, the whole theory of the internal stresses of rapidly reciprocating machinery as causing vibration, it cannot be correct to say that *acceleration* does not come under his notice.

Certainly he often ignores acceleration in his dynamical equations, but that is because he prefers to use the principles of Energy and Momentum; and our elementary text-books would do well to imitate him.

As for Dr. Lodge's hint to the sailor, it is useless and even dangerous for navigation, because it gives the distance of the offing in military land miles; instead of geographical nautical miles, as required, of sixty to the degree.

I am reminded of another delicious hint from a theorist to practical men, taken from a recent text-book of Theoretical Mechanics; the gunner is instructed not to use his favourite whip-on-whip tackle, nor the sailor to set up the backstay in the usual manner, because the theoretical writer finds the Third System of Pulleys practically useless, the strings of his model always becoming twisted.

An engineer can generally be provided with some quiet enjoyment in looking through the pages, and especially the diagrams, of our numerous treatises on Elementary Mechanics, and he will smile at the mental pabulum chopped up small for the benefit of the rising pedagogue.

In this discussion, Prof. T. W. Wright's excellent Mechanics has been lost sight of; it is a complete contrast to our ordinary elementary text-book.

I thoroughly agree with Prof. Wright that the introduction of the *poundal* has done more harm than good, and that it will never be employed, even by Electricians always working in absolute units, who will confine themselves to the Metric System.

The world will never take kindly to saying that the weight of a pound weight is 32·1912 poundals, so long as it is at rest on the table; but that the weight changes immediately to 32·2382 poundals when we toss the weight in the air.

February 6. A. G. GREENHILL.

Symbols of Applied Algebra.

I AM sorry to trouble you with one more letter on this subject. Prof. Lodge objected to the energy formula $wv^2/2g$, and stated that he could only bestow his approbation on a formula which was "independent of every system of units." His example of such a formula involved three quantities of the same kind—namely, three lengths. Being invited to give a formula involving three different quantities—*e.g.* weight, volume, and specific gravity—which should come up to his standard, he gives $W = sV$. Now this formula is certainly independent of every system of units, in the sense that it cannot be used with any known system of units (not even accurately with the C.G.S. units).

To bring out this point, I inquired how this formula is to be used with the poundal. Prof. Lodge observes, in reply, that density is not a mere number, and that specific gravity may be measured in pounds per cubit foot. The former statement is irrelevant; the latter not true if "specific gravity" is taken with the meaning with which it is invariably used.

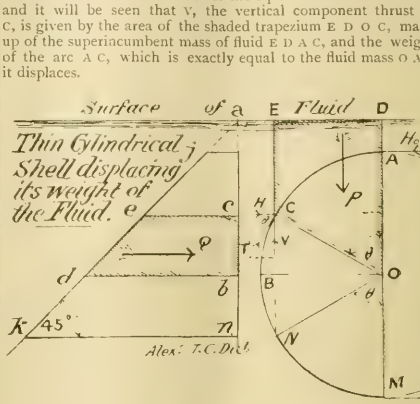
Dr. O'Reilly overlooks, I venture to think, the difference between postponing the consideration of the idea of "mass," and confusing it with "force." Of course, his comment on the formula $P/Q = f/a$ is perfectly correct. C. S. JACKSON.

Equilibrium of a Cylindrical Shell.

AMONG some work on the design of arches which Dr. Thomson, of the Science College, Poona, and myself are preparing for publication in the engineering journals, the following elegant case of the equilibrium of a circular rib occurs. As it admits of a simple physical enunciation and a simple geometrical proof, I think it may interest your readers.

A thin hollow cylinder with a uniform circular shell is submerged in a fluid, and is lying with its axis horizontal. The fluid is excluded from the cylinder by smooth face-plates of the same density as the fluid. The weight of the shell is such that the cylinder displaces its own weight of the fluid. It is evident, then, that the cylinder, as a whole, is in neutral equilibrium, at any depth below the surface. But, further, if the shell be supposed to be perfectly flexible and incompressible, it is still in equilibrium under its own weight and the fluid pressure.

Let the figure represent a ring of the cylinder one foot long, normal to the paper, and let the unit of weight be that of a cubic foot of the fluid. Consider the equilibrium of the arc A C, and it will be seen that V, the vertical component thrust at C, is given by the area of the shaded trapezium E D O C, made up of the superincumbent mass of fluid E D A C, and the weight of the arc A C, which is exactly equal to the fluid mass O A C it displaces.



Again H, the horizontal component thrust at C is given by the area of the shaded trapezium $b\,c\,e\,d$, for H_0 has to balance the whole figure $b\,j$ when the equilibrium of the quadrant A B is considered, and has to balance H together with $c\,j$ when the equilibrium of the arc A C is considered.

Now the two shaded trapeziums have their parallel sides equal each to each, so that their areas are proportional to the distances between their pairs of parallel sides. Hence

$$H : V :: Q : P :: bc : E\,D :: \cos\theta : \sin\theta,$$

and it follows that the thrust at C is along the tangent to the circle there. In the same way the horizontal and vertical component thrusts at N are given by $n\,d$ and N D, and are again proportional to cosine θ and sine θ. THOS. ALEXANDER.

Engineering School, Trinity College, Dublin, February 9.

Oysters and Copper.

As Prof. Herdman, in his interesting letter on the oyster question, appears to doubt the occurrence of copper in oysters, it may be of interest to mention that, quite recently, I examined some oysters containing this metal in considerable quantity, a single oyster yielding ·04 grammes (about $\frac{2}{3}$ grain) of copper.

Some of the oysters were light blue in colour, and others were a dark olive-green, and copper was found in both.

These oysters had been obtained from the Mumbles, near Swansea. W. F. LOWE.

Assay Office, Chester, February 4.

I AM interested to hear of Mr. Lowe's case, where he considers the oysters from near Swansea owe their colour to a very considerable amount of copper. As I stated in the concluding paragraph of my last letter (p. 293), "It is evident that there are several distinct kinds of greenness in oysters." Amongst these I cited Dr. Thorpe's recent demonstration of notable amounts of copper in oysters from Falmouth; so it can scarcely be said that I "appear to doubt the occurrence of copper." Dr. Charles Kohn has kindly re-investigated the matter for me

lately, and has determined the amounts of both copper and iron present in various kinds of oysters by electrolytic methods. He finds the green Marennes oyster contains about 0·4 mgrme. (say ·006 grains) of copper, which agrees pretty closely with the figures given by previous writers. This seems to be the normal amount present in all oysters, white or green, and due to the hæmocyanin of the blood. Dr. Thorpe, however, finds that the green Falmouth oysters have, on the average, each ·023 grains of copper, which falls to the normal amount (·006) on re-laying in another locality, and which is "obviously caused by the mechanical retention of cupriferous particles" (Thorpe, NATURE, p. 107). If Dr. Thorpe means by this that copper mud is entangled in the water and food passages of the oyster, is it not possible that, although the oyster is green, and copper is present, the colour may be due—as in most green oysters—to another cause? This mere entanglement (more or less accidental) of copper-bearing material in the passages of the oyster may also be the explanation of the extraordinarily high figure reported by Mr. Lowe—a figure (·04 grammes) as large, I may remark, as that of the *total ash* in the case of some of my oysters investigated by Dr. Kohn. W. A. HERDMAN.

Liverpool, February 6.

Immunity from Snake-Bite.

IN regard to the immunity from the danger of a second bite which a non-lethal dose of snake venom affords an animal, and also in regard to the question of antitoxin, I would suggest that the comparatively simple case of the sting of bees might be investigated.

The keeper of an apiary once told me that when he first took charge of it, he was laid up for some days by the intense inflammation due to the stings, but that he soon became quite indifferent to the venom. I myself saw him stung several times during a few minutes while he was emptying one hive into another. He had no protection over his hands and face, and, except for the sharp prick of the actual sting, he suffered no ill-effects.

May not the stinging liquid, generally assumed to be formic acid, be of the same nature as snake venom? Might not formic acid have the same effect? R. C. T. EVANS.

SUBJECTIVE COLOUR PHENOMENA.

IN a recent communication to the Royal Society,[1] I described a series of optical experiments which originated in an attempt to account for the colour phenomena exhibited by Mr. C. E. Benham's "Artificial Spectrum Top" (NATURE, vol. li. p. 113). The chief of these experiments are of an exceedingly simple character, and can easily be repeated without the employment of any special apparatus. They demonstrate the formation, under certain conditions, of transient bands of colour along the boundaries between light and dark surfaces.

Let a hole, half an inch square, be cut with a sharp knife in the middle of a sheet of thick brown paper about 15 inches square. The hole is to be covered with gummed white paper taken from the edge of a sheet of postage stamps ("stamp paper"); a small translucent window is thus formed. Across the middle of the window a common pin is to be fixed, like a bar, by means of narrow strips of stamp paper at its two ends. Holding the brown paper in the left-hand between the eyes and a lamp, the observer directs his eyes upon the translucent window; then he conceals it from view by interposing a screen, such as a thin book with a dark cover. After a few seconds, and without moving the eyes in the meantime, he suddenly withdraws the screen; then, if everything is right, and the observer is not unaccustomed to subjective visual experiments, the window will, for a moment after its exposure, appear to be surrounded by a narrow red border, while the pin also will at first appear bright red, not turning black until after the lapse of about one-tenth of a second. The effect is seen best when the lamp is at a certain distance from the brown paper. This distance must be found by trial; in my own case an eight-candle power lamp gives good results when it is about 12 inches behind the paper. The observer's eye should be 10 or 12 inches away from the translucent window.

When once the red border has been detected, it becomes very conspicuous; the difficulty in the first instance being not to see it, but to know that one sees it. The phenomenon is, without doubt, constantly met with, and habitually ignored, in daily life. Since my first observation of it I have many times noticed flashes of red upon the black letters of a book, or upon the edges of the page: bright metallic or polished objects often show a red border when they pass across the field of vision in consequence of a movement of the eyes, and it was an accidental observation of this kind that suggested an experiment like the following:—

Holding the brown paper between his eyes and the lamp, as before, the observer moves it rather quickly either up and down, or round and round in a small circle an inch or two in diameter. The moving window will, owing to persistence, form a straight or circular luminous streak, which will appear to be bordered on both sides with bright red. No person, however unpractised, to whom I have shown this experiment, has failed to see the red border at once. As before, the intensity of the illumination must be properly regulated; so also must the speed of the movement. With strong illumination the red border is very narrow, and is lined with greenish-blue; or the red colour may even be altogether absent.

The above experiments show that when a luminous image (not too bright) is suddenly formed upon the retina, it appears at first to be surrounded by a red border.

The following is a way of showing the same effect by reflected instead of by transmitted light. Two or three black lines, about as thick and as long as an ordinary pin, are drawn upon a small piece of white paper, which is placed upon a table and illuminated by strong lamp-light (not daylight). A black book is interposed between the observer's eyes and the paper, and then very suddenly withdrawn; the lines, when first seen, appear to be red, quickly changing to black. So far the observation is a rather difficult one, but by a very simple device it is possible to obliterate the image of the lines before the redness has had time to disappear; the colour then becomes easily perceptible. A thin black book is held horizontally in the right hand by its left-hand bottom corner, the thumb being uppermost; between the thumb and the book is inserted the right-hand bottom corner of a sheet of white note-paper; the upper right and left corners of the paper and the book respectively are separated, so as to form a triangular open space between them. The book is held an inch or two above the black-lined paper, covering it completely; then the hand is quickly moved from left to right in such a manner that the lines are for a moment exposed to view through the gap between the book and the note-paper, the movement being stopped as soon as the lines are covered by the paper. During the brief glimpse that will be had of the lines while they are beneath the gap, they will, if the illumination is correct, appear to be of a brilliant red hue. It must be ascertained by a preliminary trial that neither the book nor the note-paper casts a shadow upon the black lines when the gap is passing over them.

By a further simple contrivance the red images may be made visible almost continuously for an indefinite time. Upon a disc of white cardboard, from 3½ to 6 inches in diameter, two straight lines are drawn from the centre to the circumference, containing an angle of about 45°; the portion enclosed by the lines is cut out nearly up to the centre, a rim about ¼ inch wide being left at the circumference; the remainder of the disc is divided into two equal parts by a straight line from the centre to the circumference, opposite the opening, and one of these parts is painted black with ink. A pin is passed through

[1] "On Subjective Colour Phenomena attending sudden Changes of Illumination." (*Proc. Roy. Soc.*, December 17, 1896.)

the centre of the disc in such a manner that the unprepared face of the disc may rest upon the pin's head (a lady's hat-pin is better for the purpose than a small one); the pin-hole must be sufficiently large to allow the disc to turn freely. Holding this arrangement by the pointed end of the pin (which should be directed vertically upwards) above a design in black lines upon a white ground—any drawing, writing, or printing will do, provided that the lines are not too thick—the observer spins the disc by striking its edge tangentially with his finger in the direction such that the gap follows the black portion, and is followed by the white portion of the disc. If the disc makes five or six turns per second, and the beforementioned precautions as to illumination and shadows are duly observed, the black lines of the design, seen through the opening in the disc, will appear bright red, and, owing to persistence, the impression will be almost continuous.

When the disc is made to turn in the reverse direction, the lines appear to become (subjectively) blue instead of red. This appearance is partly, if not altogether, illusory. Careful observation shows that the subjective blue tint is not formed upon the lines themselves, which remain black, or rather grey, but upon the white ground just outside them. This and other experiments detailed in the paper indicate that when a dark patch is suddenly formed upon a bright ground, the patch appears for a moment to be surrounded externally by a blue border.

We have then to account for the two facts, that in the formation of these transient coloured fringes, the red originates in a portion of the retina which has not been exposed to the direct action of light, while the blue originates in a portion which is subjected to steady illumination. The effects must, I think, be attributed to sympathetic affection of the red nerve fibres. When the various nerve fibres of the Young-Helmholtz theory are suddenly stimulated by ordinary white or yellow light of moderate intensity, the immediately surrounding red nerve fibres are for a short period excited sympathetically, while the violet and green are not so, or in a much less degree. And, again, when light is suddenly cut off from a patch in a bright field, there occurs an insensitive reaction in the red fibres just outside the darkened patch, in virtue of which they cease for a short time to respond to the luminous stimulus, in sympathy with those inside the patch. The green and violet fibres, by continuing to respond uninterruptedly, give rise to the sensation of a blue border. There is reason to believe that with intense illumination, such as sunlight, these effects are reversed, the sympathetic affection of the red fibres being in such case less than that of the green and violet instead of greater.

The above-mentioned are a few among many curious phenomena which exhibited themselves in the course of my experiments. It appears probable that a careful study of the subjective effects produced by intermittent illumination would lead to valuable results, tending to clear up many doubtful points in the theory of colour vision. SHELFORD BIDWELL.

A NATIONAL PHYSICAL LABORATORY.

THE Marquis of Salisbury received at the Foreign Office on Tuesday a deputation of representatives of science who asked the Government to establish a national physical laboratory at a cost of £30,000 for buildings, and £5000 a year for maintenance. The *Times* gives the following report of the proceedings.

The deputation consisted of Lord Raleigh, Lord Lister, Sir John Evans, Sir Douglas Galton, Sir Henry Roscoe, Sir Andrew Noble, Prof. W. G. Adams, Prof. W. Chandler Roberts-Austen (Iron and Steel Institute), Prof. W. E. Ayrton, Mr. J. Wolfe Barry (President of the Civil Engineers), Prof. R. B. Clifton, Prof. G. H. Darwin, Mr. Francis Galton, Mr. R. T. Glazebrook, Prof. W. M. Hicks, Dr. J. Hopkinson, Prof. J. V. Jones, Prof. John Perry, Mr. W. H. Preece, Prof. William Ramsay, Prof. A. W. Rücker, Mr. Robert H. Scott (Meteorological Office), Mr. W. N. Shaw, Mr. J. Wilson Swan, Prof. Silvanus Thompson, Prof. W. A. Tilden, Prof. Michael Foster, and Mr. G. Griffith, Secretary of the British Association.

Lord Lister said it fell to his lot to introduce the deputation, as being President of the British Association, with which the idea of a national physical laboratory originated, and also of the Royal Society, which took an equal interest in the matter. Lord Kelvin desired him to say that he was unavoidably absent; he was in full sympathy with their object, and would have been present had it been possible.

Prof. Rücker said the scheme consisted of two parts, which, although closely connected, must be regarded as separate. The first was the proposal for the establishment of a national physical laboratory, and the second was a suggestion of a particular method for giving effect to it. There were certain types of physical investigation which were too laborious and lengthy to be undertaken by individuals or by the staff of an institution the primary duty of which was to teach, but which, on the other hand, were too closely connected with the advancement of knowledge and with research to be undertaken by the staff of a Government department. Of these types, the first was the investigation of slow changes in the properties of matter which persisted through long periods of years. Lord Kelvin had made a beginning in the investigation of these in his laboratory at Glasgow, but it was not too much to say that, although the properties to be investigated might prove to be of great importance both to scientific theory and to industry, very little was known about them at present, or was likely to be known, except by an organised effort such as they now suggested. The second task they wished to undertake was the testing and verification of instruments useful alike to industry and research. Something had been done in this country to meet this want. Standards of various kinds were in charge of the Standards and Electrical Departments of the Board of Trade, but the work which they proposed had a wider scope than that of either of those most useful departments; and the institution which in this country most nearly approached the ideal at which they were aiming was the Kew Observatory. But the permanent endowment of Kew amounted to only £447 per annum, derived from a bequest of the late Thos. Gassiot. Kew was the central observatory of the Meteorological Council, where meteorological instruments of all sorts, photographic lenses, compasses, and many other things were tested and verified; and in the last two years the average number of instruments per annum submitted to investigation had exceeded 21,000. Paris was the seat of the International Bureau of Weights and Measures; and some ten years ago the Physikalisch-Technische Reichsanstalt was founded near Berlin to carry out work of the type which he had just described. Like Kew, it received a private benefaction the gift of the late Dr. Werner Siemens, but this had been largely supplemented by the German Government. At Kew they had to thank the State for the site and the use of an old building. In Germany new buildings had been provided, at the cost of about £200,000, and the annual outlay upon the Reichsanstalt amounted to £15,000. The researches carried out, both in Berlin and in Paris, had in the comparatively short space of ten years produced remarkable results. To give one instance:—Mecurial thermometers were subject to errors which made them very difficult to use for accurate work. Researches on glass carried out in these foreign laboratories resulted in the discovery of a material free from many of the objections which might be urged against ordinary glass, and a prolonged study of the thermometer resulted in increasing the accuracy of mercurial thermometers five-fold. As a consequence of this no high-class mercurial thermometers were now made in this country, and we had to send abroad for them; in fact, at Kew itself our thermometric standards were a series of instruments which had come from Paris, and would have to be sent there to be verified if any accident or careless handling should throw a doubt upon their indications. At the Reichsanstalt there was a large department specially devoted to the investigation of problems useful to industry, and it was understood that instrument-makers, when in doubt as to the best construction of some new and delicate instrument, could obtain help from the experts in the National Laboratory. They were very anxious, therefore, that at Kew, or elsewhere, an institution should be

provided which should do for the United Kingdom that which the Reichsanstalt did for Germany, and that which, so far as its inadequate endowment would allow, Kew had attempted to do for England. The third group of investigations which they wished to undertake was also carried out in the Reichsanstalt—namely, the systematic measurements on the physical properties of various bodies, which would hereafter be data of the greatest importance, both for science and industry. There was no provision whatever for meeting this want in the United Kingdom. They thought the best plan would be to enlarge the Kew Observatory so that the work carried on there might become more nearly equivalent to that undertaken at the Reichsanstalt. The government of the enlarged observatory might be in the hands of a committee appointed by the Royal Society, or a body like the visitors of the Greenwich Observatory, appointed by the principal societies which represented science and industry. They asked for some £30,000 for buildings, and £5000 per annum.

Lord Rayleigh said the enormous sums which were being devoted in Germany in aid of science was a matter which was constantly being brought home to the scientific world; and he could not but feel that unless this country made some effort in the same direction there was very serious danger indeed that we might fall hopelessly in arrear.

Sir Douglas Galton said the assistance they asked for was only a supplement to the policy which the Government adopted a few years ago with the object of promoting technical education.

Mr. J. Wolfe Barry said he felt very strongly that every branch of applied science was greatly in want of such help to its development as would be given by the establishment of a scientific laboratory of research.

Sir Andrew Noble also supported the petition.

Lord Salisbury, in reply, said:—I have listened with very great interest to a subject which certainly is not second in interest to any that I know of, and which has been developed by persons fitter than any others, probably, in this country to expound it. It differs in some respects from deputations that we often have to receive in that it hardly deals with any controverted matter. It is often the duty of a deputation to impress upon a Minister a policy of whose general expediency he is not entirely convinced, and the deputation may take a controversial form. No such development is possible in this case. We are all of us, as we all must be—anybody who has looked into the subject at all—heartily anxious for the attainment of the objects which you advocate so far as they are practicable. But, of course, such a question as you have laid before us to-day depends not for its acceptance upon those wide conceptions of public utility that you have explained; it rather depends upon the narrower issue of finance, for there is surely no Chancellor of the Exchequer in this country who, if he was possessed of a bottomless purse, would not send you out of the room with the concession of everything in this respect that you could desire. The question is as to the furnishing of the means. And there I am afraid I am not able to give you anything like a final or a conclusive answer. I had hoped that the Chancellor of the Exchequer would have been here himself, but he has been forced to take the chair at a very important committee from which it was impossible for him to absent himself, and my courage is not equal to pledging him in his absence. I can only be quite certain that his sympathy is heartily with you, and that he would be very anxious to give such effect to the objects that you have in view as it is in his power to do. I do not think that the exertion which you require from him is quite of the limited kind which has been represented. Prof. Rücker was very moderate in his expressions, but he omitted some very important words in laying his estimate before you which he has printed in the document that he has circulated. He told you that the grant would be £30,000 for buildings, and £5000 a year. But what is said here? "It is thought that at first a grant of £30,000 for buildings and an annual grant of £5000 a year might meet the more urgent necessities of the case." Those are very terrible words to a Chancellor of the Exchequer. They hold out to him indefinite prospects of controversy, in which he himself is not made to play the most agreeable part. I never was a Chancellor of the Exchequer, but I should imagine he would look upon a deputation of this kind, not only from the high philanthropic and patriotic point of view from which he desires to regard it, but also rather as a body of men employed in contriving instruments of torture for himself. Therefore, I must reserve anything I have to say so far as the effect of those figures on his mind may go. But there is one consideration which pressed itself upon me when I read these papers, and still more when I was listening to the interesting speeches that we have heard, and that is, that the kind of security that the Chancellor of the Exchequer would probably want is not assurances of moderation upon your part, which, even if they bind yourselves, will not bind your successors; but some limitation of scope and area in the kind of assistance that you desire from him, which shall prevent, or which shall destroy, that vista of growing and unlimited expense which a Chancellor of the Exchequer is apt to associate with all great national movements of this kind. I have known movements begin with very modest thousands, and end with millions at last. There is a distinction in the objects which you seek, on which I should think it was worth while for you to lay some emphasis. So far as you are inviting the Chancellor of the Exchequer to contribute to an institution for general research, though there can be no question of the value of your objects or of their importance to the public weal, yet you will readily admit that research into the secrets of nature affords a horizon to which there is no end or bound; and he may well be startled at the commencement of a new chapter in the Estimates of whose closing periods he cannot form any conception. But there is one duty of the State which it has to perform in every age, and which it ought to perform now and to perform in increasing ratio as the demands upon it are increased by the widening aspect of science—I mean, if I may use a very grotesque word, which has been very happily used before by the authors of this paper, that the duty of standardising is a duty which the State has always performed—it is nothing but a standard institution. Sir Douglas Galton observed that the stopping of adulteration was really nothing but another form of applying a standard; and so it is in weights and measures and many other respects; and part of what you ask is really standardising, is really to furnish good standards and to furnish a means of ascertaining that the instruments are adapted to those standards and bear a proper relation to them. If the more limited work of standardising was pressed upon the State and the more extensive portion of your work, which involves general and unlimited research, was reserved—for the present, at all events—to such assistance as you might get from private munificence, I think we should have more chance of making a satisfactory beginning. This is, however, only a suggestion. I observed that all the speakers dwelt upon the enormous magnitude of the task that was before us, and I have no doubt they represented accurately not only the facts of the case, but the impression that was made on their own minds. But, still, I think in dwelling on those considerations they hardly displayed the wisdom of the serpent. It is not the magnitude of the task on which it is desirable to lay stress; it is on the importance of those portions of the task which lay immediately to your hand and on their germaneness to the duties which the State has always acknowledged and has hitherto to a great extent undertaken. In the hope that it may be found possible in the greatest possible measure to concede to you the objects which you have in view, but without attempting to pledge the bearer of the purse to the extent to which that purse would be opened, I have only to thank you heartily for your presence here to-day and for the very interesting speeches which I have heard.

Lord Lister thanked the Prime Minister for his kind reception, and the interview then terminated.

NOTES.

THE object of the strong and representative deputation which waited upon Lord Salisbury on Tuesday claims the support of all who are interested in the progress of science and industry. We reprint the *Times* report of what took place at this important meeting, and shall return to the subject next week.

M. GAILLOT has been appointed sub-director of the Paris Observatory, in succession to M. Loewy, who is now Director.

DR. YERSIN, who is now in Bombay, inoculating against the plague, has been made an Officer of the Legion of Honour.

M. SEBERT has been elected a member of the Section de Mécanique of the Paris Academy of Sciences, in succession to the late M. Resal.

A NEW research laboratory is to be erected in the Botanic Garden at Buitenzorg, Java, towards the expense of which the Government of Holland has allowed 6000 dols.

THE first portion of the great museum building of the Brooklyn Institute, being the wing of which the corner-stone was laid in December 1895, will be completed about the middle of March.

THE American scheme for a laboratory for botanical research in the Tropics appears to be assuming a definite shape, Prof. MacDougal having undertaken the duty of organising the Commission which shall visit various localities for the purpose of selecting a site. In a letter in the *Botanical Gazette* for January, Prof. Humphreys, of the Johns Hopkins University, advocates the claims of Jamaica, where there are already two botanic gardens, at Castleton and Gordon-Town, and where the Governor, Sir Henry Blake, is interested in biological science.

WE have received a second paper by Dr. P. Zeeman, "On the influence of magnetism on the nature of the light emitted by a substance." But, with the exception of some theoretical speculations, it does not give much additional information on the experimental discovery announced in the preliminary notice, a translation of which appeared in our columns last week. The paper confirms, however, the main fact, that a sodium flame placed between the poles of a magnet shows a widening of the D lines equal to about one-fortieth of the distance between them. When examined by a Rowland grating, the edges of the widened lines are found to emit circularly polarised light, the direction of rotation being opposite on the two sides.

THE Edouard Mailly prize has just been awarded by the Brussels Academy of Sciences for the first time. It was founded by the late M. Mailly, and amounts to 1000 francs, to be given every fourth year to the person or persons who have most assisted in the extension of astronomical knowledge in Belgium. The first award has been made to the editorial committee of *Ciel et Terre*, viz. MM. C. Lagrange, E. Lagrange, A. Lancaster, L. Niesten, W. Prinz, and P. Stroobant.

THE President of the French Republic visited the Pasteur Institute on February 10, and Dr. Roux was able to show him cultivations of the plague microbe. In the course of his remarks to the President, Dr. Roux observed that the microbe has little power of resistance, and is easily destroyed by antiseptics and by a temperature of 140°. He pointed out, however, that the plague bacillus had the power of retaining its vitality in the soil, and it is on account of this property that epidemics favoured by dense population and insanitary surroundings are perpetuated in Eastern countries.

ACCORDING to the Rome correspondent of the *British Medical Journal*, there appears to be no doubt that Dr. Giuseppe Sanarelli has discovered the bacillus of yellow fever. He will publish an account of his discovery in the next number of a leading Italian hygienic publication, which will be issued in the course of the next few weeks. *La Nazione*, of Florence, has published an article, sent by a correspondent in Montevideo, which states that for some little time Sanarelli hardly believed in his success, but in August his experiments were so clear that he was certain of the discovery of the microbe, and he then occupied himself with the preparation of the serum. His experiments were very extensive; he vaccinated more than 2000 animals, including rabbits, goats, sheep, monkeys, and a few horses. The results of the treatment are definitely reassuring, and in October 1896 he decided to announce confidentially to the President of the Republic of Uruguay the results that have crowned his studies in the origin and cure of yellow fever. If this remedy be truly efficacious, Dr. Sanarelli will obtain the reward of 150,000 scudi (£30,000) offered by the Brazilian Government for the discovery of such a remedy.

SIR H. TRUEMAN WOOD will read a paper upon the "Reproduction of Colour by Photographic Methods," at the Society of Arts on Wednesday next, February 24. The paper will have special reference to M. Chassagne's process of photography in colours, described in NATURE of February 4, and results obtained by this and other processes will be shown.

The Council of the Royal Photographic Society of Great Britain have awarded the Progress medal of the Society to Prof. Lippmann, for his discovery of the process of producing photographs in natural colours by the interference method. The rules by which this medal is given preclude the award of more than one in any year, and since its institution in 1878 ten medals only, including the one mentioned above, have been awarded.

AN interesting paper was read on Thursday last, by Prof. J. C. Bose, at the Indian Section of the Society of Arts, on the promotion of advanced study of physical science in India. The lecturer made some valuable suggestions for the encouragement of original research in India, among which may be mentioned the establishment of post-graduate scholarships and fellowships by Indian Universities. One of the great drawbacks in the prosecution of physical research in India is the want of suitable laboratories. It is to be hoped that this vital want, which stands in the way of original investigations in science, will soon be removed. Scientific men in Europe are greatly interested in the recent contributions to science made by India, and they welcome Indian investigators as their co-workers in advancing natural knowledge.

FROM the *Gardener's Chronicle* we learn with regret that Baron Constantin Ettingshausen, the palæontologist and botanist, has died at Graz, at the age of seventy-one. Deceased was originally a doctor of medicine, but devoted all his time and energies to botany and palæontology. He was engaged for some time in arranging palæontological collections in the British Museum (Natural History). He was the author of several works on botanical subjects, and wrote a large number of papers, which were published in the *Proceedings* of the Royal Society, and of other learned bodies.

WE notice also with regret the announcement of the death, at Headington, near Oxford, of Mr. Henry Boswell, the eminent bryologist. Mr. Boswell had not only studied the mosses of Britain, but had an intimate acquaintance with foreign species, and his knowledge was utilised by many correspondents in different parts of the world. In his early days his attention was directed to the study of flowering plants, but subsequently he developed a greater fondness for the study of bryology. He possessed a large collection of mosses, which it is hoped will be secured by the University. In recognition of his services to bryological science, Oxford University, in 1887, conferred upon him the honorary degree of Master of Arts.

THE following are among the announcements of the deaths of men of science abroad:—Dr. Nikolai Zdekauer, St. Petersburg, member of the Imperial Academy of Sciences, and distinguished for his work to advance hygiene and the knowledge of epidemics; Herr Alois Rogenhofer, formerly curator of the Imperial Natural History Museum in Vienna; Dr. Hermann von Noerdlinger, formerly professor of forestry in Tübingen University; and Dr. G. D. E. Weyer, professor of mathematics and astronomy in Kiel University.

WE are sorry to see the announcement in the *Times* that Prof. Charles Tomlinson, F.R.S., a successful and distinguished teacher and writer in both science and literature, died on Monday, at his residence in Highgate, in his eighty-ninth year. He was elected on the Council of the British Association for the Advancement of Science in 1864, a Fellow of the Royal Society in 1867, a Fellow of the Chemical Society in the same year, and was one of the founders of the Physical Society. He was for many years Lecturer on Experimental Science at King's College, held the Dante Lectureship at University College, 1878–80, and was Examiner in Physics to the Birkbeck Institution. In science he was the author of many handy text-books on natural philosophy, meteorology, and natural history, and contributed numerous papers, the results of original research, to the *Transactions* of the Royal and Chemical Societies. In 1854 he edited "Tomlinson's Cyclopædia of Useful Arts, Mechanical and Chemical, Manufactures, Mining, and Engineering." In biography he wrote the lives of Smeeton, Cuvier, and Linnæus, and the notices of scientific men in "The English Cyclopædia of Biography." In literature he was the author of "The Inferno of Dante, translated into English Tierce Rhyme"; "Herman and Dorothea, translated from the German Hexameters of Goethe into English Hexameters"; "Essays, Old and New"; "The Chess Players' Manual," and many contributions to literary and scientific magazines.

AN announcement, which will arouse a good deal of interest among biologists, was made at a recent meeting of the New York Academy of Sciences. Mr. Bashford Dean reported that he had obtained a fairly complete series of embryos of *Bdellostomum*, including upwards of twenty stages from cleavage to hatching. *Bdellostoma*, as the name is usually written, is a form very closely allied to *Myxine*, the hag-fish, which is abundant off the northern coasts of Europe. Hitherto the development of the Myxinoids, with the exception of one stage of segmentation, has been entirely unknown, though many European zoologists have spent much time and labour in unsuccessful endeavours to obtain material for its investigation. The developing eggs of *Bdellostoma*, which are quite similar to those of *Myxine*, were obtained by Mr. Dean in the course of collecting operations carried on at Puget Sound, California, by a party of zoologists from Columbia University, New York, in the summer of last year. A number of the eggs and larvæ of a form allied to Chimæra were also secured. The results of the study of this material will be of the greatest interest and importance. After the mystery of the reproduction of the eel had been explained by Grassi, there were only two well-marked types of vertebrates whose development still baffled investigation; and the difficulties in these two cases appear to have been at last overcome.

THE first number of the second decade of the *Kew Bulletin of Miscellaneous Information* is almost entirely devoted to a "List of Kew Publications, 1841–1895." It consists of more than eighty pages of titles of independent publications, or of very numerous and important contributions to journals, containing a record of work done either by members of the Kew staff, or by others working in the Gardens, the Herbarium, or the Jodrell Laboratory. In addition to the *Icones Plantarum*, *Botanical Magazine*, and other serials issued from Kew, the list includes all the more important Colonial Floras, such as Bentham's of Australia, Hooker's of New Zealand, Grisebach's of the British West Indies, Seemann's of the Fiji Islands, Baker's of Mauritius, Hooker's of British India, and others; also important monographs, such as Baker's of the Fern-Allies, Bromeliaceæ, and Amaryllideæ, Massee's of the Myxogastres, many of the orders in Martius's *Flora Brasiliensis*, &c. When to this is added such works of first-class importance as Sir W. J. Hooker's "Genera Filicum," Hooker and Bentham's "Genera Plantarum," Hooker's "Himalayan Journals" and "Botany of the *Erebus* and *Terror*," Bentham's "Handbook of the British Flora," Hooker's "Student's Flora," Hemsley's "Handbook of Hardy Trees, Shrubs, and Herbaceous Plants," and, to crown all, the "Index Kewensis," it will be seen that there is some justification for the statement that the list "represents a volume of work which probably is not surpassed by that of any other institution in the world."

We learn from the February *Journal* of the Royal Geographical Society that the first gold medal of the American Geographical Society of New York, the fund for which was given by the late General Cullum, has been awarded to Lieut. Peary, and was presented to the explorer at the recent annual meeting of the Society. Of Mr. Peary's many services to the geography of the Arctic regions, that which is selected as the special ground for the award is his delineation, in 1892, of the coast-line of Greenland and the consequent demonstration of its insular character. Lieut. Peary, after returning thanks for the medal, proceeded to unfold his plan for a new expedition, which is to aim at reaching the North Pole, a plan which has already been endorsed by the New York Society. Having given it as his opinion that the results of recent expeditions serve to show that the only feasible route by which to attain the North Pole is that by Smith Sound and the north-west coast of Greenland, he pointed to the important work to be done in those regions, in addition to the reaching of the Pole. He proposes the raising of sufficient funds to enable the work of the expedition to be continued, if need be, for ten years. It is proposed to go to Sherard Osborn Fjord, or further, in a ship manned by a minimum crew, and—having taken on board *en route* several picked families of Eskimo—the people and stores would be landed, and the ship sent back. During the autumn sledging season he would advance supplies north-eastward along the coast by short and rapid stages, taking advantage also of the brilliant winter moons. The party itself would follow stage by stage, living like the Eskimo in snow-houses, so that in early spring it should have already reached, with the bulk of its supplies, the northern terminus of the North Greenland Archipelago, whence, ice conditions being favourable, a dash for the Pole would be made with the lightest possible equipment, with picked dogs and two of the best Eskimo. Each succeeding summer the ship would attempt to reach the base, whence the series of *caches* already formed at each prominent headland would supply a line of communication with the advanced station.

THE Seismological Committee of the British Association has just sent out a circular inviting co-operation in an endeavour to extend and systematise the observation of earth-movements. The cost of an instrument to record such movements, with photographic material to last one year, is about 50*l*. The first object the Committee has in view is to determine the velocity with which motion is propagated round, or possibly *through*, the earth. To attain this, all that is required from a given station are the times at which various phases of motion are recorded; for which purpose—for the present, at least—it is considered that an instrument recording a single component of horizontal motion will be sufficient. Other results which may be obtained from the proposed observations are numerous. The foci of submarine disturbances, such, for example, as those which from time to time have interfered with telegraph cables, may possibly be determined, and new light thrown upon changes taking place in ocean beds. The records throw light upon certain classes of disturbances now and then noted in magnetometers, and other instruments susceptible to slight movements; whilst local changes of level, some of which may have a diurnal

character, may, under certain conditions, become apparent. Persons who are willing and able to participate in the work of obtaining such records, are requested to communicate with the Seismological Committee, British Association, Burlington House, London, W.

WE have received from the National Observatory of Athens the numbers of the *Bulletin Mensuel Seismologique* for August, September, and October last. The number of shocks observed in Greece during these three months are respectively 24, 27, and 24. The majority were very slight, and were felt by only a few persons; but the large number recorded is a good test of the valuable work done by the new Geodynamic Section, which the Director of the Observatory has placed under the charge of Dr. Papavasiliou.

DR. JOHANNES BUCHWALD contributes to the *Mittheilungen von Forschungsreisenden und Gelehrten aus den deutschen Schutzgebieten* a paper on the distribution of plants in West Usambara, from observations made by himself during six months' residence at Muafa, and on three journeys extending over the whole of the neighbouring mountain region. The floras of the plain and mountain districts are dealt with under separate headings, and special attention is devoted to the species which, while properly belonging to the one region, make their way into the other.

A PLAN, on a large scale, of the newly-founded New York Botanical Garden, accompanies the *Bulletin* of the Garden for January. The same number contains also reports of the Committees to which were entrusted the plans for the arrangement of the Gardens and Museum, as well as Prof. Britton's address on Botanic Gardens, given at the last meeting of the American Association, which comprises a slight sketch of the principal botanic gardens of the world.

THE *Botanical Gazette*, the leading botanical journal of the United States, commences the present year with a staff of three editors and thirteen associate-editors, representing the four American Universities of Harvard, Cornell, Michigan, and Missouri, and the following foreign centres:—Geneva, Padua, Berlin, Paris, Tōkyō, Bonn, Cambridge (England), Copenhagen, and Stockholm. The inclusion of Tōkyō in the list is indicative of the great activity of biological studies in Japan. Besides original articles, the *Gazette* has admirable abstracts of important papers published in foreign botanical journals.

A BIBLIOGRAPHY of the published writings of Dr. P. L. Sclater, F.R.S., has been published as *Bulletin* 49 of the U.S. National Museum. Many years ago the publication of a series of bibliographies of representative American naturalists was begun by the Museum, and five bulletins of this type had been published previous to the present one. Though the original intention was to confine the series to the work of naturalists carrying on researches in America, Dr. Sclater has paid so much attention to American ornithology that it was considered most desirable to widen the scope and devote a bulletin to his contributions to the subject. The result of acting upon this decision is a bibliography running into 135 pages, arranged chronologically, and in lists of new families and genera described, new species described, and species figured.

THE meteorological observations made at Rousdon Observatory, Devon, during 1895, and the reduction of observations for the lustrum 1891–95 and the decade 1886–95, are contained in a volume which Mr. Cuthbert E. Peek has just distributed. In addition to the statistical contents, the report contains a valuable account of a comparison of the records of a Kew pattern Robinson anemometer with those of a pressure-tube anemometer. The sum of the mean hourly velocities obtained from the pressure-tube record was compared with the recorded run of the caps of the Robinson anemometer for each month. The results are, on the whole, very consistent, and show that, for almost all velocities, the pressure-tube record amounts to only about eleven-fifteenths of the mileage recorded by the Robinson. In other words, assuming the velocity shown by the pressure-tube to be correct, the factor of the Robinson should be 2·2. Mr. Peek thinks that the true factor of the Kew pattern, or standard size, Robinson anemometer is sufficiently close to 2·2 as to make it safe to accept that value for getting the real velocity of the wind from its records.

A VERY attractive guide to Stockholm, containing numerous illustrations, and useful hints to tourists, has been issued by the Swedish Tourists' Club. The guide should be seen by all who propose to visit the beautiful capital of Sweden during the forthcoming summer, when the great Scandinavian Art and Industry Exhibition will be open.

A GENERAL index to the first fifty volumes of the *Quarterly Journal* of the Geological Society, has been compiled and edited by Mr. L. L. Belinfante, Assistant Secretary of the Society. Part i., comprising the letters from A to L, has just been published. It need hardly be said that the complete index will be of great service to geologists. Another useful publication issued by the Geological Society is the author's and subject index to the geological literature added to the Society's library during last year.

THE first number of *The Middlesex Hospital Journal* has been sent to us, and it is a very creditable production. Among the contents is a paper, by Mr. Henry Morris, on the diagnosis and treatment of stone in the bladder. Referring to the use of Röntgen rays in the diagnosis of renal and vesical calculi, it is shown that calculi compound of uric acid and urates are not likely to be revealed by the rays, especially if the rays have to pass through the adult skeleton to reach them. On the other hand, stones which have phosphates or phosphate or oxalate of lime in their composition can be discovered by Röntgen rays. A portrait of the late Mr. J. W. Hulke, F.R.S., reproduced by the Swan Electric Engraving Company, forms a striking frontispiece to the *Journal*.

THE Museums Association exists for "the promotion of better and more systematic working of museums throughout the kingdom." In order to promote this object, the Association meets in a different town each year. Last year it met at Glasgow, and the report of the proceedings at the meeting, edited by Mr. E. Howarth and H. M. Platnauer, has lately been published by Messrs. Dulau and Co. To curators of museums the volume is invaluable. Among the subjects dealt with in it are type specimens in botanical museums, by Mr. E. M. Holmes; colour tinting and its application to microscopic work, by Dr. G. Bell Todd; descriptive geological labels, by Mr. Herbert Bolton; electrotypes in natural history museums, by Mr. F. A. Bather; chemistry in museums, by Mr. G. W. Ord; and suggestions made by Huxley in 1868 for a proposed natural history museum in Manchester, contributed, with Huxley's original pen and ink sketches, by Mr. W. E. Hoyle.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Miss M. Hewens; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. C. W. Hutchings; a Yellow-shouldered Hangnest (*Icterus tibialis*) from Brazil, presented by Mr. W. H. St. Quintin; a Ring-tailed Coati (*Nasua rufa*) from South America, deposited; two Painted Frogs (*Discoglossus pictus*), South European, received in exchange; four Varied Field Mice (*Isomys variegatus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

PRIZES IN ASTRONOMY.—The Belgian Government has offered a sum of 300,000 francs, without distinction of nationality, on the occasion of the Exhibition to be held this year in Brussels, to the authors of the best solutions of some important questions selected by special Committees of the different Sections. The problems which more especially interest us, namely those on astronomy, are as follows (the values of the 1st, 2nd, and 3rd prizes being 900, 600, and 500 francs respectively).

A. Construct an apparatus by which relative measures of the value of g on board ship may be made.

B. Construct an apparatus to show the effects similar to those of the germination of the canals on Mars, and which may explain the actual observed phenomena.

D. Invent a means by which planetary details may be photographed as clearly as they can be observed.

E. Find a method by which the sun can be observed at any time as if it were totally eclipsed.

F. Indicate a sure method of determining the amount and direction of movement of the solar system.

Prizes of 300 and 200 francs are offered for the authors of the best answers to the following :—

A. Investigate, from the point of view of computation of astronomical observations, whether the formulæ of Laplace, relative to the movement of rotation of the earth, are or are not more exact than those of Oppolzer.

B. Improve in some way the measures made with the meridian circle (elimination or determination of personal error, instrumental corrections, &c.).

C. Write a critical essay on the fundamental principles of mechanics, and differentiate between what is purely rational and what is in the domain of experience.

D. Improve in some point the actual state of our knowledge of cosmogony.

E. Improve our knowledge of gravity, either by a new discussion of old observations or by new methods.

F. Improve the magnetic chart of any country, either by a fresh discussion of old observations or by the use of new ones.

G. The theory of the motion of rotation of the terrestrial pole.

H. Give complete theoretical formulæ for the variation of latitudes, and determine by them the periods theoretically.

I. Investigate whether a new term for the secular acceleration of the moon can exist.

DOUBLE STAR MEASURES.—Vol. x. Part 1 of the publications of the *Washburn Observatory* contains the observations of double stars, made with the 40 cm. Clark equatorial telescope of this observatory between the years 1892 and 1896. The stars selected were for the most part well-known binary systems in rapid motion; but additions have at times been made, among which were eleven stars of very slow relative motion included in the list of circumpolar stars selected by Otto Struve for observation as comparison stars. Only nights on which the "seeing" was sufficiently good for the employment of high magnifying powers were used. The director, Mr. George Comstock, states, with regard to the possible error due to the position of the observer's head: "I have uniformly held my head in such a position during the observations that the line joining the eyes was either parallel or perpendicular to the line joining the star images." The measurements of distance were made by placing the micrometer threads upon the discs of the stars. In the cases of very close and difficult stars, another method was adopted, applied only when the distances were below 0″·5. A discussion of the probable errors shows that for distances less than 0″·60, a single estimate of distance may be assumed constant and equal to $\pm$ 0″·040. The coordinates of the stars in the list are referred to the equinox of 1880·0.

LUNAR PHOTOGRAPHS.—The February number of the *Bulletin de la Société Astronomique de France* contains an interesting article, by M. Camille Flammarion, on lunar photography. The reader will find there some excellent reproductions of the Paris negatives, the latter equalling, if not surpassing, any photographs obtained. A magnificent phototype, from a photograph taken February 14, 1894, shows the moon nine days from the lunation, Copernicus standing out magnificently clear on the terminator. All the details are wonderfully sharp, and the contrast leaves little to be desired. M. Loewy is to be congratulated on the high state of efficiency which he has attained in his photographic investigations of the lunar surface.

REPORT ON THE CORAL REEF AT FUNAFUTI.[1]

Prefatory Note by Prof. T. G. Bonney, F.R.S., Vice-Chairman of the Committee.

IN presenting, as desired by the Committee, Prof. Sollas's report on the attempts to ascertain, by boring, the structure of the atoll of Funafuti and on other investigations simultaneously undertaken, I avail myself of the opportunity of expressing the gratitude which is felt by its members to our friends in New South Wales, who have given such real and substantial help, especially by the loan of machinery and skilled workmen, in putting the project into execution; and among them chiefly to Prof. Anderson Stuart (who has been practically another Secretary in Australia), Prof. Edgeworth David, Mr. W. H. J. Slee (Chief Inspector of Mines), and Sir Saul Samuel (the Agent-General of the Colony in England). I shall venture also to acknowledge gratefully the services of Captain Field and the officers of H.M.S. *Penguin*, and the unstinted labour which has been given by Mr. W. W. Watts, our Secretary in London, in carrying out our plans. In conclusion, may I express, speaking for myself, my earnest hope that another attempt will be made to determine the true structure of an atoll. I think, however, that our experience on this occasion shows that the attempt can be much more easily made, and with a far greater probability of success, if Australia instead of England be the base of operations, and I trust that before long the colony of Sydney will initiate an expedition, and we shall co-operate with them as cordially as they have done with us.

Report of Prof. Sollas, F.R.S.

H.M.S. *Penguin* having come to anchor in the lagoon of Funafuti on the afternoon of Thursday, May 21, Captain Field at once landed with Lieut. Dawson, Ayles (the foreman of the boring party), and myself, and we proceeded to make arrangements for our work on the island. A site for boring was chosen near the sandy beach of the lagoon, conveniently situated for the landing of gear, less than half a mile to the south and west of the village of Funafuti, and near the village well, which supplies a small amount of brackish but drinkable water. The work of landing was commenced the next morning, and completed by May 26. The erection of the boring apparatus was at once taken in hand, and on June 2, twelve days after our arrival on the island, all was in readiness for commencing operations. On June 3 the 6-inch tubes were driven into the sand, and by June 6 they had been advanced 30 feet; the 5-inch pipes were then entered, and everything made ready for inserting the diamond crown and commencing to drill on Monday, June 8. On June 10 it was arranged that the work should proceed by shifts, so that the drilling might be carried on continuously day and night. During the first shift the crown had been advanced 20 feet, making the total depth then attained 52 feet 9 inches; during this shift, fragments of highly cavernous coral rock were brought up in the core barrel from a depth of between 40 and 50 feet.

On June 11, a depth of 85 feet having been reached, it was found necessary to ream the hole preparatory to lining, and by June 15 the necessary reaming and lining had been completed. Up to this, although we had been somewhat disappointed at our slow rate of progress, occasioned partly by the unfavourable nature of the ground and partly by the frequent failure of our machinery, we had anticipated nothing worse than the possibility of finding our allotted time exhausted before we had reached a depth of 1000 feet; but now, on setting the crown to work, it very soon ceased to advance, and Ayles shortly afterwards came to me to announce that, in his opinion, the boring was a failure. Nevertheless, some further progress was subsequently made, and on Tuesday, June 16, a depth of 105 feet was attained. It then became once more necessary to ream and line the hole. Attempts to ream were continued all through Wednesday and Thursday, but without success; sand poured into the hole, and the reamer could not be driven through it. Efforts were made to remove the sand by a sand-pump, but proved unavailing, the sand flowing in faster than it could be pumped out. Ayles assured me that it was impossible to descend another foot, and that he considered further labour as time and money thrown away. We decided therefore to

[1] "Report to the Committee of the Royal Society appointed to Investigate the Structure of a Coral Reef by Boring." By Dr. W. J. Sollas, F.R.S., Professor of Geology in the University of Dublin. Received December 1896. Read, February 11, 1897.

abandon this borehole, and to recommence operations on another site, if possible in solid rock.

The structure of the ground passed through in the abandoned borehole was as follows (Fig. 1):—

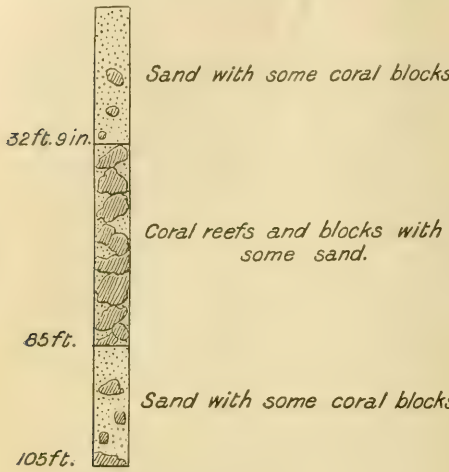


FIG. 1.—Section of the abandoned borehole.

Although I knew of many places where solid rock forms the surface of the ground, it was very difficult to find one to which we could transport our machinery; the difficulties of landing on a rocky shore rendered several promising spots inaccessible by sea, while the absence of wheeled vehicles or even wheels, and the nature of the ground, seemed to put transportation by land out of the question.

At last, however, Mr. Hedley pointed out to me a portage called Luamanif, and used by the natives for dragging their canoes from the lagoon to the seaward side of the island, which at this place is very narrow, about 70 yards across. As this seemed a good landing-place I submitted it to the consideration of Captain Field, who, after a personal examination, agreed that we might safely make use of it. Ayles and his party were then set to work to sink trial-pits on the line of the portage; one of these, situated 70 feet from the high-water mark on the seaward face of the reef, was sunk 12 feet through sand and blocks of coral, when operations were brought to a close owing to the influx of sea-water at high tides. Two other pits were then commenced nearer the sea and a little to one side (north) of the portage, at the margin of the solid platform of rock, which extends down to the growing edge of the reef, and which is covered by the sea at high water. These passed through sand and fragments of coral. In the most northern of the two pits the sand was somewhat consolidated, and so, proceeding a few yards further north, as far in that direction as it would have been possible to transport our machinery, we opened another pit, which was sunk for a depth of 11 feet through fragments of coral, crystalline coral limestone, and partly consolidated sand. The bottom of the pit was 2 feet below the seaward margin of the reef, and as we were not inconvenienced by an influx of sea-water, and Ayles was of opinion that the rock would "stand," we decided to make our new venture at this spot (Fig. 2). Taking into consideration the difficulties of transporting our apparatus, I do not think a more favourable locality could have been chosen; it was close to the very edge of the rocky platform, which is so hard that Darwin, speaking of a similar platform in the case of another reef, says, "I could with difficulty, and only by the aid of a chisel, procure chips of rock from its surface"; and as near the sea as it was prudent, or even possible, to go. Indeed, we had at first some doubt as to whether our pumping pipes would "live" in the surf of the ocean margin, and feared that the high-water spring tides might inundate the shaft; our fears in these respects, however, proved to be groundless.

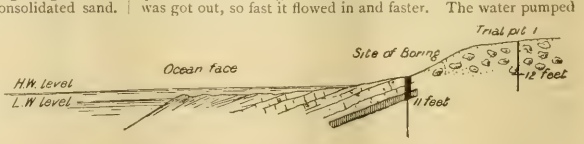

FIG. 2.

Captain Field and myself were impressed with the need of additional boring apparatus, and he proposed that Ayles should go to Sydney to see if it could be procured. I gave much anxious consideration to this project, and discussed it with my colleagues, Messrs. Hedley and Gardiner, and with Ayles. The information I received from Ayles was not encouraging. He stated that we should require a complete equipment of lining tubes, from 10 inches down to 2½ inches in diameter, that 10-inch tubes were not to be had in Sydney, and that even if we succeeded in obtaining all the appliances we required, the success of the boring would even then by no means be assured.

For a doubtful result I did not feel justified in incurring the certain increase in our expenditure which a journey to Sydney would have involved; the question of time had also to be considered, for had Ayles gone to Sydney we should on his return have been commencing our boring at or after the date the Committee had considered it would have been completed. Finally, it appeared that the new locality we had chosen for our work offered fair prospects of success.

The shaft already sunk to a depth of 11 feet was then timbered with Pandanus logs, and arrangements made for carrying down a hole by jumping with a 6-inch chisel. Ayles spoke of getting as far as 50 feet by this means, and then lining the hole with 6-inch tubes, but after sinking 4 feet he declared it impossible to proceed further in this way; the chisel could not be made to continue sinking in a straight line, the labour was too exhausting, and progress very slow. It was decided, therefore, to begin boring, Ayles being very hopeful, as the hole "stood" well. On Thursday, June 25, we accordingly made arrangements to shift our boring gear to the new site, and by Saturday, June 27, this work was completed, chiefly by native labour, at a cost of about £10. The boilers were rolled along the beach, the rest of the machinery taken by water, and all subsequently dragged, rolled, or carried across the portage. Lieut. Waugh lent us valuable assistance, during the absence of the *Penguin*, in this work.

Boring was commenced on Friday, July 3, and by 5 o'clock we had sunk another 4 feet; progress then became rapid, and on Saturday evening, when work was knocked off, we had descended in all 46 feet. Very little "core" was obtained, however, and at times the boring bit met with very little opposition as it advanced, seemingly passing through a vacant space. Since the water pumped into the hole no longer flowed out above, but found its way out by some communication with the sea below, it was impossible to determine whether or not some sand might have been present. It was clear, however, that the coral rock through which the "bit" advanced was highly cavernous.

On Monday the hole became filled with fallen fragments and some sand; it was evident, therefore, that the sides would not hold, and so recourse was had to lining; by Thursday, July 9, the hole had been reamed and lined down to 45 feet, and the work of boring was resumed. On pumping, we had the satisfaction of seeing the water flowing out of the top of the hole; but our joy was short-lived, for, on Monday, June 13, the water was again lost. On Tuesday, July 14, we had reached 65 feet, passing for the last 20 feet through sand and coral. Subsequently we attained a depth of 72 feet, and could then proceed no further. We worked all Thursday and Friday with the sand pump, but with no success; the bottom of the hole was surrounded by quicksand containing boulders of coral, and as fast as the sand was got out, so fast it flowed in and faster. The water pumped down disappeared through the sand, boring and *à fortiori*, reaming was impossible, and the tubes could not be driven owing to the interspersed boulders. Had the tubes been provided with steel driving ends, we might have forced them down; as it was, the effect of driving them was simply to curl in the lower

end. Had we been provided with 4-inch tubes we could have made a fresh start, and might have descended another 30 or 40 feet, but even then ultimate success would not have been ensured, for the chance of meeting again and again with intermixed sand and coral remained always open, and every such encounter would have required lining tubes of diminished calibre.

Baffled in all our endeavours, and no other part of the island offering more hopeful prospects of success, we had no alternative but to abandon the undertaking, and on July 30 we were taken from the island in the *Penguin* and returned to Fiji. On landing there we had the mortification to learn that additional apparatus was then on the way to Funafuti, our friends in Sydney having, with great generosity, at once despatched machinery for driving in sand on receipt of a letter I had sent informing them of the failure of our first borehole. We had had no reason to expect such spontaneous assistance, and even had we been fortunate enough to have remained on the island till the machinery arrived, we should probably not have accomplished the object we had in view, though we might possibly have carried the borehole down to a depth of about 400 feet.

A very free communication must have existed between the borehole and the sea, for whenever a big roller broke upon the reef the rods lifted, and after the lining had been withdrawn, water spurted out of the borehole with the fall of every wave. The open nature of the reef is further indicated by the fact that the sea-water rises with every tide to fill certain depressions, which occur in many places in the middle of the island; as the tide ebbs this water flows away down fissures, often so rapidly as to form little whirlpools.

Wherever I have seen the reef growing it has always presented itself as clumps or islets of coral and other organisms with interspersed patches of sand, and the borings would seem to indicate that it maintains this character for a very considerable depth, and possibly throughout. The structure of the reef appears indeed to be that of a coarse "sponge" of coral with wide interstices, which may be either empty or filled with sand.

As regards the nature of this "sand," it is important to observe that it does not consist of coral débris; this material and fragments of shells forming but an insignificant part of it; calcareous algæ are more abundant, but its chief constituents are large foraminifera, which seem to belong chiefly to two genera (*Orbitolites* and *Tinoporus*). It covers a considerable area of the islands, and has accumulated during the memory of the inhabitants to such an extent as to silt up certain parts of the lagoon. This and the abundant growth of corals and calcareous algæ, such as *Halimeda*, lead to the belief that the lagoon is slowly filling up.

A suggestion has recently been made that more light is likely to be thrown on the history of atolls by a study of ancient limestones in the British Isles than by boring in existing reefs. The first essential, however, for such a study would appear to be a knowledge of the structure of living atolls, for, without this, the identification of others forming a part of the earth's crust, might remain more or less a matter for conjecture. So far as the structure of Funafuti has been proved by borings, it is scarcely what a field geologist might have anticipated, and if deposits of a similar nature and origin should have been encountered in, say, the mountain limestone, it is doubtful whether, previous to the borings in Funafuti, their interpretation would have been easily reached.

While the boring has proved a failure, the other objects of the expedition have been attained with complete success. Messrs. Hedley and Gardiner have made a thorough investigation of the fauna and flora, both land and marine. Dr. Collingwood has obtained a good deal of information of ethnological interest, and we all have brought home a fairly complete collection of native implements and manufactures. A daily record was kept of maximum and minimum temperature, and of the readings of the dry and wet bulb thermometers.

The most important contribution, however, and one that I think must, in certain details greatly modify our views as to the nature of coral reefs, is afforded by the investigations of Captain Field. Never before have soundings, both within and without an atoll, been so closely and systematically made, and the results seem to me commensurate with the care and pains that have been taken to secure them. Four series of soundings, "Sections," as they are termed on board the *Penguin*, have been run from the seaward face of the reef outwards. How close together the soundings were made is shown in the following table, which Captain Field has kindly permitted me to copy from his order book:—

Depth	0— 40 fathoms	every	10 yards.
,,	40— 70	,,	20 ,,
,,	70—100	,,	30 ,,
,,	100—150	,,	40 ,,
,,	150—200	,,	50 ,,
,,	200—300	,,	60 ,,
,,	300—400	,,	70 ,,
,,	400—500	,,	80 ,,
,,	500—600	,,	90 ,,
,,	600—700	,,	100 ,,
,,	700—800	,,	200 ,,

The profiles obtained by the four series are closely similar, and, as regards one important feature, almost identical. This

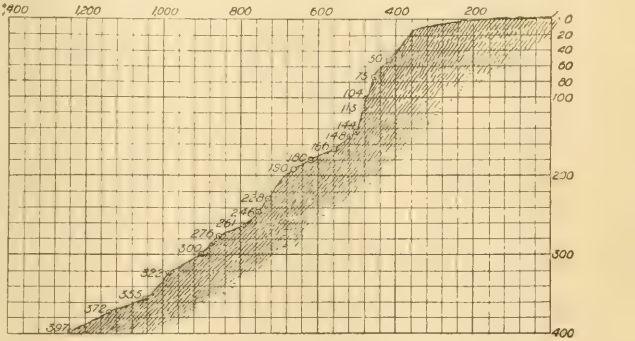

FIG. 3.—Section D—Horizontal measurements in yards; vertical measurements in fathoms. The section is drawn to true scale.

is the sudden change in slope that occurs at or about 140 fathoms. Speaking generally, one may describe Funafuti as the summit of a submerged conical mountain, the base of which, at a depth of 2000 fathoms, is a regular ellipse, 30 miles long by 28 miles broad. It rises with a very gentle slope, which gradually grows steeper as it ascends, till from 400 to 140 fathoms it has an angle of 30°; at 140 fathoms an abrupt change occurs, and the slope becomes precipitous, making an angle of from 75° to 80° for the greater part of its course, till it passes into the shallow flats of the growing reef. It is difficult to resist the impression that it is the upper 140 fathoms (840 feet) which represents the true coral reef. A convex curvature of the profile between 166 and 261 fathoms is probably a talus, produced by an accumulation of coral débris (Fig. 3).

The conical mountain below the 140 fathoms line, with its parabolic slope, is suggestively similar to a volcano; but, if so, its crater must have been immense, 10 miles across at least. A volcano, 12,000 feet in height, with a crater 10 miles in diameter, is, however, not an unknown phenomenon; within the limits of the Pacific we may cite Haleakala, in Maui, Sandwich Islands, as closely comparable.

A part of my work while on the island was the construction of a geological sketch map, part of which is shown in Fig. 4; its interest chiefly centres in a broad expanse near the Mission Station, where the two narrow limbs of the island meet, or, if it be preferred, whence they extend. Towards the seaward side this broad corner is occupied by a mangrove swamp, the floor of

which is formed by a dead coral reef, constituted almost wholly of two species, one a massive Porites, and the other *Heliopora cærulea*. For a great part of the day this floor lies bare and dry, the frayed ends of the Heliopora standing like broken reeds, 6 inches above its surface, and the great clumps of Porites forming a series of stepping-stones of equal height. Neither of these corals stands long exposure to the air; on Funafuti they require constant submergence, and we are thus led to regard their upper surface as marking what was at one time the level of low tide in the swamp; but since the present level of low tide is below the level thus indicated, some change must have occurred in the level of low tides. Not necessarily an elevation of the reef: Darwin has admirably discussed this explanation, and it is quite conceivable that some change in local conditions, such as the exclusion of the sea by the growth of the hurricane beach, may have produced a local alteration in the height of the tides. The swamp communicates with the sea by pits in its floor, which enter subterranean channels running seawards. These passages are so narrow that the tide rises and falls in the swamp much more slowly than in the open sea. To determine whether any change of level has taken place, it thus becomes necessary to compare the highest and lowest water level of the swamp with that of the sea or of the lagoon. I accordingly levelled across the island from the lagoon to the sea, crossing the swamp on the way, and found that the high-water level at spring tides is 1 foot 10 inches below high-water (spring tides) of the lagoon, so that given free access of the sea, the Heliopora reef would be covered 1 foot 10 inches deeper than at present; but it is now submerged from 10 inches to 2 feet 2 inches at high water springs, and would accordingly be submerged from 2 feet 8 inches to 4 feet, with free access of the sea. The range of spring tides is at least 6 feet, as I learn from Lieut. Dawson, but I am not quite sure that an extreme range of 9 feet 8 inches has not been observed. Taking, however, the smaller number, it becomes clear that for a considerable part of the day, the reef would be exposed to the air. It is not likely that under these conditions the corals would continue to live, and, I think, therefore, that the reef must have undergone some slight elevation, to the amount, perhaps, of 4 feet. This conclusion is in accordance with Dana's view, and is supported by observations on some other features of the island, such, for example, as the occurrence of an interrupted line of low cliffs, sometimes passing into a series of pinnacles, generally about 4 feet in height, as measured from low-water level. In the annexed section (Fig. 5) the cliffs are further from the land than is usually the case. These cliffs consist of a consolidated breccia of coral fragments, and are now in process of denudation, as is

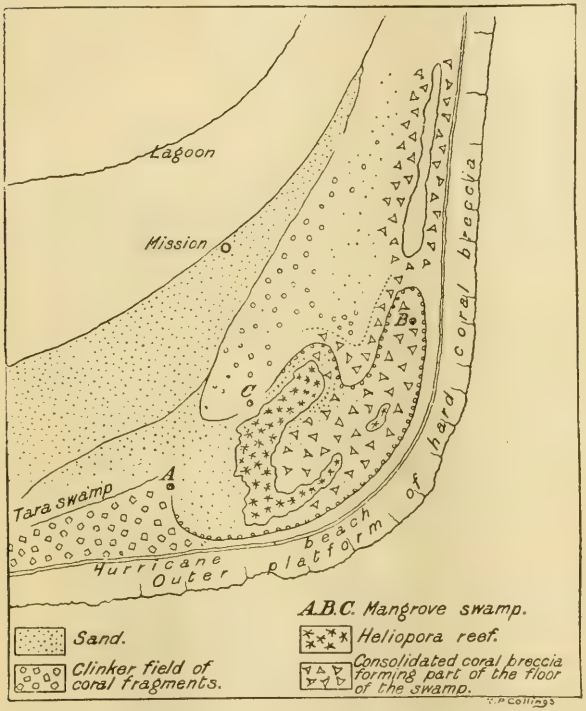

FIG. 4.—Corner of Funafuti, showing Mangrove Swamp and Heliopora Reef.

FIG. 5.

the coral platform which extends from them, up to and under the hurricane beach. This breccia was probably formed and cemented together when the reef stood at least 4 feet lower than at present, and was produced by the breakers driving fragments of corals from the seaward edge of the reef into the lagoon, as they are now doing over the isthmuses, submerged at high tide, which connect the several islets of the atoll together.

If it should prove true, as I do not doubt, that one of the latest episodes in the history of the reef has been an elevation of, say, 4 feet, then in the immediately antecedent stage, the reef must have been a wash, or, perhaps, wholly submerged, and the present terrestrial fauna and flora must have reached it subsequent to its elevation, as sea drift, or have been introduced by human agency.

In conclusion, I would add that to myself the soundings obtained by Captain Field appear to support Darwin's theory of coral atolls; there remains, however, one very important branch of the subject which stands in need of renewed investigation, and this is the bathymetrical limit to coral life. Not till I had obtained a close acquaintance with the difficulties of dredging on the steep side of an atoll did I recognise on how frail a basis our accepted conclusions rest. It is a task difficult enough to get up corals from the lagoon in comparatively shallow water; from the sides of the reef it is well-nigh impossible. To obtain dead corals from great depths proves little; living corals are generally found with dead associates, and the latter are the more readily detached and brought to the surface. The weight of the evidence we already possess is admittedly in favour of a comparatively shallow bathymetrical limit, but much remains to be done before we can speak of any limit as definitely ascertained.

THE INSTITUTION OF MECHANICAL ENGINEERS.

ON Thursday and Friday, the 4th and 5th inst., the annual general meeting of the Institution of Mechanical Engineers was held in the theatre of the Institution of Civil Engineers, in Great George Street. The President (Mr. E. Windsor Richards) occupied the chair. The Secretary read the report of the Council, from which it appeared that the Institution continues to grow in numbers and to accumulate capital, it having an income of over 7000*l.* a year, and an expenditure of about 5000*l.*, the accumulated excess of receipts over expenditure being now over 46,000*l.* The Institution will shortly have a house of its own. Hitherto its offices have been a suite of rooms on the ground-floor of one of the buildings in Victoria Street, Westminster, a rent of 710*l.* being paid. The new building will be situated at the Storey's Gate to St. James's Park—that is to say, just at the bottom of Great George Street. The plans, which were exhibited at the meeting, show a handsome building, and as the front looks right on to the Park, the Mechanical Engineers will be very pleasantly housed. There will be a large lecture theatre, so that the Institution will no longer have to depend on the hospitality of the parent engineering Institution for a place to hold its meetings. Although this will naturally be a convenience, it will be with regret that the pleasant association between the two Institutions of host and guest will be severed. In looking at the new building of the Institution of Civil Engineers and the house of the Mechanical Engineers, now springing into existence only a few yards off, one cannot but think with regret what might have been done had the various Institutions devoted to engineering interests joined forces, and built a really commanding building, worthy, at the same time, of being a public monument to applied mechanical science. The Institutions of Civil Engineers, Mechanical Engineers, Naval Architects, Iron and Steel, and Electrical Engineers are all prosperous societies. Of course the Civil Engineers and Mechanical Engineers overshadow the others in wealth and influence, but they would have lost nothing by joining forces, for the accommodation afforded in the building could have been appropriated according to the amount contributed. There were naturally some difficulties in the way, but these could have been overcome. However, the chance of Great Britain, the birthplace of steam engineering, having a worthy home of engineering science is now past, and we can only look with appreciative interest on the efforts of the different societies to house themselves independently, but in a relatively modest fashion. The new building of the Mechanical Engineers will be finished in eighteen months. It has been kept back by difficulties with the London County Council.

There were three papers set down for reading at the meeting. They were:—

(1) Fourth Report to the Alloys Research Committee. By Prof. W. C. Roberts-Austen.

(2) Partially immersed Screw Propellers for Canal Boats, and the Influence of Section of Waterway. By Henry Barcroft.

(3) Mechanical Propulsion on Canals. By Leslie S. Robinson.

The Report to the Alloys Research Committee alone calls for any extended notice.

Mr. Barcroft's paper was read; and it had, however, the good effect of calling forth from Mr. S. W. Barnaby a very clear exposition of some points in connection with screw propulsion; and also a speech from Mr. Thornycroft, which, together, will serve to put the matter in a true light in the *Proceedings*.

The report of Prof. Roberts-Austen gave, firstly, some general considerations respecting the present position of the research; secondly, it dealt with the copper zinc alloys, known as the brasses; and thirdly, with certain relations between the fusibility and strength of alloys; and this involved considerations as to the constitution of alloys generally. An account was also given of an experimental investigation which was undertaken with a view to measure the molecular mobility of solid and molten metals, known as diffusion.

In the series of researches, of which a part was described in the paper, the author had attempted to find how far the properties of metallic masses are dependent on atomic movement and molecular grouping. This part of the paper contains so striking a lesson on the value of scientific investigation of problems of a constructive or industrial nature, that we will quote Prof. Roberts-Austen's introductory passage to this section in full. It ought to be unnecessary to do so, but the self-called "practical man"—who is really the most short-sighted and unpractical man in existence—has been so much in evidence of late, and has received so much support from a section of the technical press, that a corrective may well be administered.

Prof. Roberts-Austen, referring to the course followed in the report, says:—

"The mechanical properties of alloys of definite series of metals have assumed less prominence than the principles which affect alloys generally; and the result has been that, although the course adopted hardly needs justification, the practical bearing of the investigation may have seemed to be somewhat remote. The devotion of years of labour, for instance, to tracing the relations of alloys to saline solutions, would appear at first sight to be of less practical importance than determining the mechanical properties of alloys by the aid of testing machines. Establishing the analogy between alloys and saline solutions has, however, been eminently fruitful in practical results; for it has enabled the mechanical properties of alloys to be explained, and even to be predicted. It has been easy to show that the property of liquation possessed by saline solutions while freezing—which consists in rejecting a certain quantity, often very minute, of a fluid portion of the mass, and distributing or relegating it to a definite position in relation either to the mass as a whole, or to the individual crystals—is now recognised as being of fundamental importance in determining the mechanical properties of varieties of iron and steel and of alloys generally. This subject of liquation will always be identified with the work of the Alloys Research Committee, and its history is interesting. Its origin is French (Levol, *Annales de Chimie et de Physique*, vol. xxxvi., 1852, p. 193; vol. xxxix., 1853, p. 163); but much experimental work in this connection was published more than twenty years ago in a paper of my own (*Proceedings* of the Royal Society, vol. xxiii., 1874–5, p. 481); and the present Report will contain references to the latest phases of the inquiry, which may also be claimed as the outcome of the labours of this Committee. Attacking the problem of the constitution of alloys from the atomic point of view has, moreover, been fruitful in results; for it has enabled the influence exercised by the relative atomic volumes of the alloyed metals upon the mechanical properties of the mass of metal to be clearly revealed."

The original problem proposed for consideration of the Alloys Research Committee was, "Are the mechanical properties of metals and alloys connected with their atomic volumes?" This

question, the author says, "has been definitely answered in the affirmative."

In dealing with the copper zinc alloys, the author reminds us that it is seldom an alloy solidifies sharply or at one temperature, as water does. There are generally at least two freezing points; and in the industrial brasses, which never contain more than 45 per cent. of zinc, only three of the freezing points were referred to at first, although the scientific interest of the rest was considered later on. The chief point of interest in the paper was the consideration of the eutectic alloys. Of the several breaks in the curves of cooling points of most alloys, the first usually represents the falling out of a more or less pure metal, or some compound of the metal, from the cooling alloy. A second and sometimes a third break indicates the solidification of a eutectic alloy, that is a fusible metallic or "mother liquor," which solidifies at a definite temperature. In the copper zinc series there are several of these eutectic alloys.

Guthrie introduced the designation "eutectic" alloy to denote the most fusible alloy of two or more metals, comparing it to the mother liquor of a salt solution, which remains fluid after the bulk of the salt has crystallised out. The recording pyrometer shows that as regards alloys the case is really far more complicated. Many alloys consist, when fluid, of more than one solution; and each of the several solutions leaves, on cooling, a solid deposit and a fluid mother liquor. These mother liquors, however, do not usually unite with one another; and a complicated set of conditions is established, when the temperature has fallen sufficiently low for the whole mass to become solid. Each of these metallic mother liquors is a eutectic alloy. Some alloys—the lead-tin for instance—are of a simple character, and when fluid have only one eutectic alloy, that is, the deposits fall out from a single mother liquor. All the alloys which are used for the sake of their strength appear to be highly complicated. Thus in the alloys of copper and zinc there are at least four eutectic alloys, and in the copper-tin series there are at least six.

The composition of eutectic alloys does not in general correspond to simple atomic proportions of the component metals, and the author considers there are theoretical reasons for supposing that a eutectic alloy cannot possibly be a chemical compound. It should be noted that in the cooling curves of some alloys, solidification, as shown, takes place over a somewhat long range of temperature. The point at which one constituent begins to crystallise has been called the higher freezing point, and the temperature at which the eutectic alloy solidifies out is called the lower freezing point. These two points are indicated by separate evolutions of heat. That the lead-tin series has more than one freezing point, is illustrated in a familiar way which has considerable industrial importance. A plumber making a "wiped joint" uses a solder containing 66 per cent. of lead, and its pasty condition is due to the fact that it has two widely separated points of solidification, the alloy consisting of granules of solid lead in a fluid mother liquor.

The facts above given lead up to a consideration of the mechanical properties of brasses, and the relation of these properties to the freezing point curve. In dealing with this part of the subject, the author had recourse to a series of diagrams exhibited on the walls of the theatre. Without the aid of these it will be impossible for us to treat the matter at all completely, even from the point of view of a brief abstract. Indeed the report—which is of great length—is so full of matter that we cannot hope to do more than give a few of the most prominent facts, which may serve to afford our readers an idea of its scope. Those interested in metallurgical research will naturally go to the original for fuller information. The method of investigation pursued was to heat an alloy in a steel cylinder and squeeze out the eutectic by hydraulic pressure; the temperatures being noted, until finally a comparatively infusible residue is left. The several portions were then analysed, and the results of the analyses were given in an appendix. The results were discussed by the author in detail; the dominant fact disclosed being that the maximum strength in the series of cast brasses occurs in the alloy containing 60 per cent. of copper. This alloy has practically only one freezing point. Further additions of zinc cause a rapid diminution of tensile strength and extensibility. The explanation given was that in these alloys the compound CuZn is unaccompanied by free copper. In a series the summit of the curve representing extensibility coincides with the first appearance of the upper eutectic which falls out from the alloy that contains 71 per cent. of copper. This eutectic probably consists of a mixture of copper with the compound CuZn. The mixture of these soft and hard substances produces great strength, as is evident from the fact that the strongest alloy of the series consists almost entirely of this eutectic; but the presence of the eutectic naturally diminishes the extensibility of a mass which contains more than a small amount of it.

The addition of small amounts of iron to certain alloys of copper and zinc (Sterro and Aich's metal) is next discussed by the author. The reason of the remarkable increase of strength thus produced has hitherto been obscure, but the facts are disclosed by a comparison of the cooling curves given in the report. The alloy selected contained 61 per cent. of copper and 39 per cent. of zinc; and in the absence of iron there was a low eutectic point in the cooling curve at about 450° C. or 842° F., evidently due to the presence of a eutectic, which constituted a source of weakness. The added iron, however, entered into combination with the eutectic, forming with it a less fusible compound; for a cooling curve then showed that the low eutectic point was absent, and that the source of weakness had been removed. Moreover, the main solidifying point of the Aich's metal was higher than that of the brass: which in itself is an indication of augmentation of strength. The facts thus established are probably of wide importance in metallurgical practice; and where strength is desired, it would appear to be advisable, whenever a cooling curve reveals the presence of a low eutectic in an alloy, to add some third metal which will diminish the fusibility of the eutectic. Aich's metal, when compared with brass of the same composition but without the 1½ per cent. of iron, is greatly superior in strength. If it owes this superiority to the fact that a eutectic alloy does not remain fluid as the mass cools, it might be anticipated that the relatively high tenacity of Aich's metal would be maintained at temperatures at which the brass would become weak.

We have not space to follow the author further in his valuable and interesting research. He shows how the action of impurities is made clearly evident in connection with eutectic points, and has some most instructive remarks on the diffusion of metals, the latter a most important section of the report. He also gives an account of improvements in the recording pyrometer by which great delicacy in recording is secured. The report concludes with a comparison of the thermo-junction with the air thermometer.

A good discussion, opened by Sir William Anderson and Sir William White, followed the reading of the report; but we have preferred to devote the space at our disposal to the report itself, as containing the most important matter. It may be said, however, that the tone of the discussion was entirely favourable to the report, its practical importance and value being dwelt upon both by the engineers and metallurgists present.

DR. YERSIN, AND PLAGUE VIRUS.

IN view of the importance which attaches to Dr. Yersin's discovery of the plague virus and its anti-toxin, the following notes on his work may be of interest.

When a youth of twenty, Yersin had the rare good fortune to obtain an entrance to the Institut Pasteur. The extraordinary ardour with which he devoted himself to his work, rapidly won for him the admiration and respect of all his colleagues. When little more than a student, Roux signalled him out to assist him in those important researches on the toxin of diphtheria which have since become so memorable, and which were communicated to the scientific world under the joint names of the master and his pupil.

While at Tonkin, in the spring of 1894, he received the request from the French Government to proceed to Hong Kong to study the plague which had recently broken out there. Yersin started off on his mission, and arrived in Hong Kong a few weeks after the plague had commenced its terrible career in that city—a career which had already claimed the lives of 300 Chinese, and which was yet to exact a tribute of over 100,000.

Yersin describes how, on reaching Hong Kong, he found the authorities busy rapidly erecting temporary hospitals, the existing accommodation being quite inadequate to cope with the widespread dimensions of the epidemic. He obtained permission to erect a small hut within the precincts of the principal hospital; and there, in a concentrated plague atmosphere, he

took up his quarters, and hastily improvising a laboratory, commenced his investigations.

So far the plague had confined itself to the insanitary Chinese quarters of the city; and Yersin mentions that the wretched cabins occupied by the natives were often not only without windows of any kind, but were sunk below the level of the ground, which, combined with the shocking overcrowding which prevailed, converted such dens into plague-incubators of the most fulsome and dangerous character.

In these infected districts, one of the first things which attracted Yersin's attention was the extraordinary number of dead rats which lay about in all directions in the houses as well as in the streets; but, on inquiry, he soon learnt that this rat-mortality was a well-known forerunner of the plague, that the latter usually attacks animals such as rats and mice, and in the country districts swine and buffalos, before it touches human beings. An examination of these dead rats showed that their symptoms differed in no way from those which characterise the plague in man, and the extreme susceptibility of these animals furnished Yersin at once with a valuable means of tracking out the virus. His first step was to make careful examinations of the bubonic material present in the tumours which accompany the disease, and here he discovered immense numbers of a short bacillus which appeared to be almost exclusively in possession of the field. These he found were readily stained, and could be cultivated with ease in the usual bacterial media. Further investigation showed that these same bacilli were invariably present in the ganglia and liver and spleen of plague patients; that they were, however, rarely to be found in the blood, and then but in small numbers, and usually only in rapidly fatal cases a short time before death.

Healthy rats and mice inoculated with pure cultures of this bacillus succumbed to the typical plague symptoms; and Yersin had thus accomplished the first step in his investigation—the identification of the specific virus of plague. Yersin was at first of opinion that rats were the principal disseminators of the disease, for healthy mice shut up with a dead plague-stricken rat, rapidly developed the disease and succumbed; but he noticed later the curious fact that, in the little room where he carried out his *post-mortem* examinations, immense numbers of dead flies were scattered about in all directions. He, therefore, determined to ascertain if this wholesale slaughter of flies had any connection with plague infection; so taking some of these insects, and first removing the head, wings and feet, he pounded up their bodies in broth. An examination later of the liquid exhibited masses of bacilli closely resembling the now familiar plague microbe; to place their identity beyond doubt he inoculated some of this broth into mice, with the result that the latter died of plague. That flies materially assisted in the spread of the disease was thus established.

With the slender accommodation and primitive means at his disposal, it was impossible for Yersin to further pursue his investigations, and prepare a plague anti-toxin, and he, therefore, forwarded cultures of his bacillus to the Institut Pasteur, and from here, in the course of the following year, was published the memoir describing the production of the anti-plague serum which is now being so urgently requisitioned for service in India. The bacillus was found to be pathogenic for not only rats and mice, but for the other animals of an experimental laboratory, rabbits and guinea-pigs.

The attempt was first made to vaccinate these animals by means of the toxin, but filtered cultures of the bacillus produced no effect whatever; so that the plan was adopted of heating cultures to 58° Centigrade, and inoculating the dead bacilli. If the latter are injected in sufficient quantities, they are capable of killing the animal; but if a smaller quantity of the liquid containing them is employed, then it acts as a vaccine, and the animal is protected from a subsequent lethal inoculation of the virus, and its serum subsequently acquires protective properties. From success with small animals the attempt was made to immunise large animals, such as horses. For this purpose virulent plague-cultures, capable of killing a mouse in two days, were employed, and the liquid containing these living microbes was injected into the horse's veins. The reaction was rapid and intense, and lasted a whole week, after which the fever abated, and the animal slowly recovered. A long interval—twenty days—was allowed to elapse before a second injection was attempted; but this time, although an equally virulent culture was employed, in the same quantity as before, the symptoms were less pronounced, and passed away more rapidly, and it was found possible to both gradually increase the quantity and diminish the interval between the several injections. At the end of six weeks the first trial was made of the curative properties already attained by the serum, and the results were regarded as extremely satisfactory and encouraging. To confer immunity to plague infection on a mouse, it required $\frac{1}{15}$th of a cubic centimetre of serum, administered twelve hours *before* the virus was injected; to cure animals after plague infection, 15 cubic centimetres of serum were required to be inoculated twelve hours *after* the virus had been introduced. The large quantity of serum necessary in these first experiments for curative purposes, was due to the short time during which the immunising process had been carried on. It will be remembered that in diphtheria the time required to train a horse's serum up to the proper protective pitch is a question of months, and in the case of anti-venomous serum a matter of as much as fifteen months; thus a treatment of six weeks only is a very short time for the serum to exhibit immunising properties. That the most remarkable therapeutic value attaches to anti-plague serum as now elaborated at the Institut Pasteur in Paris, is shown by the success which has recently followed its application in undoubted cases of plague at Amoy, by Yersin, now Director of a Pasteur Institute at Nha-Trang in Annam.

In conclusion, it may be asked, How long is England to rest content to knock as a humble suppliant at the door of foreign institutes for assistance when overtaken by disaster, as is now the case in India? Why should Paris supply the means for relieving the suffering of our fellow-subjects in India?

The answer and reasons for that answer are, alas! but too well known to require repetition here; and we can only hope that in the future, at present dim and obscure, the barriers which now so formidably impede medical progress in this country may yield before the enlightened pressure of public opinion.

G. C. FRANKLAND.

THE "BAZIN" ROLLER BOAT.

IN NATURE of December 3, 1896, we gave a short notice of the new roller-boat the *Ernest Bazin*. From a paper recently read at the Society of Arts by M. Emile Gautier (*Journal* Society of Arts, January 22), the following further particulars are taken.

The *Ernest Bazin* was launched a few months ago at Saint-Denis, and was then taken down the Seine to Rouen, where she is being fitted with her engines and machinery. As soon as these are completed an experimental trip will be made across the Channel, and it is anticipated that the vessel will in the course of about six weeks be anchored in the Thames. This experimental vessel has a displacement of 280 tons; its length is 131 ft. 3 in., and width 38 ft. 9 in. The framework and hull are supported on six lenticular hollow wheels 32 ft. 10 in. in diameter, about one-third of which will be immersed. The engines, cargo, cabins, &c., are placed on a platform resting on a framework carried on the axles of the wheels. The engines are constructed to develop 750 horse-power; 550 of which will be used for the propeller, and 200 horse-power for driving the three pairs of wheels. With this power an ordinary steamer of a similar tonnage would not steam more than 18 or 19 knots. It is expected that the *Ernest Bazin* will attain double this speed. The principle on which the vessel is constructed is the substitution of the rolling motion of great wheels for the ordinary gliding motion of the hull of the vessel through the water, in order to minimise friction. An ordinary ship with its hull gliding through the water represents the disc pushed forward without a rotary motion being imparted to it. As it is compelled to cut the water in front of it, and to drive it back longitudinally, it would soon cease to move forward did it not receive a fresh impulsion at every moment. If, however, the vessel were supported by revolving buoys, it is contended that it would possess all the advantages of the disc, to which a rotary as well as a forward motion is given. The effort, instead of being exercised longitudinally, is exercised partially downwards, vertically, so that the resistance is reduced in a considerable degree.

As the result of calculation the rotary speed of the wheels has been made one half greater than the speed of translation.

In the discussion which followed the reading of the paper, the speakers, while declining to prophesy as to the results to be attained, seemed to be of opinion that the difficulty of construction would increase very rapidly with the increase in size, owing to the great strain which would be imposed on the

platform in rough weather, and that to obtain the necessary strength the weight would become excessive.

Practically the carrying part of the structure rests on six floating vessels coupled together by a framework. It does not follow that because this principle as applied to the lightly-constructed canoes used by the natives of the Polynesian Islands is successful, that it could therefore be applied to the enormous structure required for an Atlantic liner. The *Calais Douvre* and other coupled boats which have been built for the cross-Channel passage, have certainly not proved a success.

M. Bazin, the inventor, is an engineer well known in France for the originality of his ideas, and for the invention of a submarine machine that served for the attempt to raise the Spanish galleons sunk in Vigo Bay; also for inventions in connection with gold-washing machinery, dredgers, cranes, &c. His roller-boat will no doubt attract a great deal of attention when it arrives in the Thames.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The degree of Doctor of Science will be conferred on Dr. Nansen at a special congregation to be held at 1 p.m. on March 16.

Prof. E. E. Barnard, of the Yerkes Observatory, Chicago, is to exhibit his photographs of the Milky Way, and other celestial objects, in the Lecture Theatre of the Cavendish Laboratory, at 4 p.m. on February 20.

Dr. A. C. Haddon is this term giving two well-attended classes (one elementary and one advanced) in physical anthropology at the Anatomy School.

An examination for scholarships and exhibitions in natural science and engineering will be held at Trinity College on March 15. Details may be learned on application to the tutors.

THE Cornwall County Council have had to further increase the salary attached to the lectureship on fisheries to £350 per annum, to enable them to secure a competent instructor.

AT a meeting of the Council of the Royal College of Surgeons, on Saturday last, the following resolution was adopted (subject to the approval of the Royal College of Physicians): "That the Royal College of Physicians of London and the Royal College of Surgeons of England, in full accord with their previous action, express the earnest desire that her Majesty's Government will, at the earliest opportunity, reintroduce a Bill for the reconstitution of the London University by statutory commission on the general lines of the report of the Cowper Commission, and do assure the Government that such a course will have their approval and support." It was further resolved that if the Royal College of Physicians adopted the foregoing resolution, copies of it should be forthwith forwarded to the Lord President of the Council, Mr. Balfour, and the Senate of the University of London.

A PLEA for the establishment of a National University at Washington is made in *Science* of February 5. It is suggested that the University should be developed from the national institutions already existing at Washington. "Workers in the different Government divisions and others having the proper preliminary education could, on presenting a thesis showing original work and passing an examination, receive the doctorate of philosophy, and this would qualify them as a civil service examination for promotion. The present Commissioner of Education, and perhaps the Regents of the Smithsonian Institution, could govern the University. Examiners could be appointed from leading representatives of science and learning, who would meet yearly for a week of convocation in Washington. We believe that, without radical changes, and with nominal expense, there could be established at Washington a National University likely to become the world's greatest University."

AN annual report, received a few days ago, tells us that the past year was more than usually interesting in the history of the Glasgow and West of Scotland Technical College, as being the centenary of the foundation of Anderson's College, which received its charter of incorporation from the magistrates of the City of Glasgow on June 9, 1796. Besides being the oldest member of this composite institution, the interest attaching to Anderson's College—apart from the fame of its medical school, now a separate institution—lies in the fact that it was the progenitor of mechanics' institutions and the pioneer of technical education in this country. The record of successes of past and present students testifies to the soundness of the instruction given. The College is extending its operations rapidly over the West of Scotland, and, as its name implies, it is now more than a Glasgow institution. We notice that Mr. G. F. Scott Elliot has been appointed lecturer in botany, in succession to the late Mr. Thomas King, who occupied that position for many years.

THE fifth annual report of the Technical Instruction Subcommittee of the City of Liverpool, which has reached us, shows that the high standard of efficiency was maintained during 1896. Most educationists will agree with the Chairman, who says, in his prefatory remarks, that "it will be a considerable advantage to the cause of higher education generally when it is recognised, by legislative authority, that specialised technical instruction can only properly be carried on as part of a general scheme of secondary education, and when means are provided for encouraging and developing general secondary education without attempting to force it too soon towards specialisation." The detailed report of the Director shows that no part of the legitimate work of a local system of technical instruction has been neglected. The teaching of science and modern languages has been further improved and developed in the secondary schools, special attention being very properly directed towards the provision of every convenience for the necessary amount of practical instruction in chemistry and physics. Side by side with this provision for young boys and girls, we find an efficient system of evening classes in commercial and technical subjects for young men who have started upon the serious work of life. The Committee have shown their appreciation of their good fortune in having a University College at hand by helping it to the extent of £1700 during the past year, which has been marked by a much needed extension of the chemical laboratories, and by the establishment of a new Natural History Museum.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, January.—"On the stability of a sleeping top" is the abstract of a lecture delivered by Prof. Klein before the Society at the Princeton meeting, October 17, 1896. It will be remembered that Prof. Klein delivered four lectures "On the theory of the top," at the sesquicentennial celebration of the University. In these latter an attempt was made to simplify the formulæ for the motion of a top by turning to account the methods of the modern theory of functions. The later lecture before us considers from the same standpoint a much more elementary question, viz. the stability of a top rotating about an axis directed vertically upwards. The point of support is supposed to be fixed. When the rotation is very rapid the behaviour of the top is as if its axis were held fixed by a special force. Some interesting results are arrived at.—Bibliography of surfaces and twisted curves, by Dr. J. E. Hill, consists mainly of extracts from a paper read before the Society in May last. It attempts to represent a compilation and classification of all articles, with certain exceptions, upon these surfaces and curves which have been published during the present century. The paper itself should be, judging from these extracts, extremely useful to students.—Linear differential equations is a review, by Prof. M. Böcher, of Schlesinger's "Handbuch der Theorie der Linearen Differentialgleichungen," and, like the previous work by Prof. Böcher in the *Bulletin*, is thorough. The writer's conclusion is that though the book fails to meet some of the demands which it seems to him may fairly be made of a handbook, it is certain to fill an important place in a mathematical library, owing to the great amount of information which it contains in accessible form.—Messrs. R. W. Willson and B. O. Peirce furnish a table of the first forty roots of the Bessel equation $J_0(x) = 0$ with the corresponding values of $J_1(x)$. This is a paper which was presented to the Society at its summer meeting, September 1, 1896.—The final article, not counting the notes and publications, is entitled "Notes on the Theory of Bilinear Forms," and is by Prof. H. Taber. It was read at the November meeting.

Wiedemann's Annalen der Physik und Chemie, No. 2.—On the dissipation of electricity from a conductor into the air, and on the influence exerted by an increase of temperature of the conductor upon this process, by A. Oberbeck. A thin wire, to which an electric charge is imparted, loses its charge more

readily in air when hot than when cold. The difference between a positive and a negative charge is also more strongly marked at high temperatures, the negative charge being more rapidly dissipated.—Point discharge potentials in air and hydrogen, by K. Wesendonck. The quantity of negative electricity discharged into hydrogen is greater than the quantity of positive electricity discharged at the same potential, but the initial discharge potentials are not necessarily different.—The atomic theory in natural science, by L. Boltzmann. The conception of the atom cannot be finally superseded by the differential equation as applied to a *continuum*, since the latter is itself based ultimately upon the conception of a discrete structure, even in such applications as Fourier's theory of thermal conductivity. The atom has also the advantage of greater immediate clearness and picturesqueness over the differential equation, whether it really exists or not.—On discharge rays, and their relation to kathode and Röntgen rays, by M. W. Hoffmann. Discharge rays are contained in the spark discharge in air, hydrogen, and nitrogen at ordinary or low pressures. They exert no photographic action, but may be discovered by their property of imparting luminescence to solid solutions of manganese sulphate in gypsum when heated to a temperature below incandescence (thermo-luminescence). They are intercepted by mica, quartz, fluorspar, and other solids, unless produced at low pressures. They proceed in straight lines, and are not deflected by a magnet. They differ from ultra-violet light in their power of penetrating air, and not fluorspar. They are not reflected by solids.—Platinised electrodes and determinations of resistance, by F. Kohlrausch. The solution used by Lummer and Kurlbaum for making bolometers, viz. one part platinum chloride, to 0·008 lead acetate and 30 water, gives a platinum black, which is very useful for platinising electrodes. It facilitates the use of smaller electrodes for alternate-current resistance measurements, and gives a well-marked minimum of telephone effect.—Electric moment of tourmaline, by W. Voigt. This was determined by breaking the tourmaline into fragments, and was found to be 33·4 C.G.S. units.—A new formula for spectrum waves, by J. J. Balmer. The author substitutes for the infinite geometrical progression in Kayser and Runge's formula a closed term, and gives the frequencies for the lines of each series in the form $A - B/(n+\epsilon)^2$.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 21.—"On Reciprocal Innervation of Antagonistic Muscles." Third Note. By C. S. Sherrington, F.R.S., Holt Professor of Physiology, University College, Liverpool. Received December 29, 1896.

If transection of the neural axis be carried out at the level of the crura cerebri in, *e.g.* the cat, there ensues after a somewhat variable interval of time a tonic rigidity in certain groups of skeletal muscles, especially in those of the dorsal aspect of the neck and tail and of the extensor surfaces of the limbs. The details of this condition, although of some interest, it is unnecessary to describe here and now, except in so far as the extensors of the elbow and the knee are concerned. These latter affect the present subject. The extensors of the elbow and the knee are generally in strong contraction, but altogether without tremor and with no marked relaxations or exacerbations. On taking hold of the limbs and attempting to forcibly flex the elbow or knee a very considerable degree indeed of resistance is experienced, the triceps brachii and quadriceps extensor cruris become under the stretch which the more or less effectual flexion puts upon them, still tenser than before, and on releasing the limb the joints spring back forthwith to their previous attitude of full extension. Despite, however, this powerful extensor rigidity, flexion of the elbow may be at once obtained with perfect facility by simply stimulating the toes or pad of the fore foot. When this is done the triceps enters into relaxation and the biceps passes into contraction. If, when the reflex is evolved, the condition of the triceps muscle is carefully examined, its contraction is found to undergo inhibition, and its tenseness to be broken down synchronously with and indeed very often accurately at the very moment of onset of reflex contraction in the opponent prebrachial muscles. The reaction can be initiated in more ways than one, electrical excitation of a digital nerve or mechanical excitation of the sensory root of any of the upper cervical nerves may be employed; I have seen on one occasion a rubbing of the skin of the cheek of the same side effective.

Similarly in the case of the hind limb. The extensor muscles of the knee exhibit strong steady non-tremulent contraction under the appropriate conditions of experiment. The application of hot water to the hind foot then elicits, nevertheless, an immediate flexion at knee and hip, during which not only are the flexors of those joints thrown into contraction, but the extensors of the knee joint are simultaneously *relaxed*. Electric excitation of a digital nerve or of the internal saphenous nerve anywhere along its course will also initiate the reflex.

January 28.—"On the Capacity and Residual Charge of Dielectrics as affected by Temperature and Time." By J. Hopkinson, F.R.S., and E. Wilson. Received December 15, 1896.

The major portion of the experiments described in this paper have been made on window glass and ice. It is shown that for long times residual charge diminishes with rise of temperature in the case of glass, but for short times it increases both for glass and ice. The capacity of glass when measured for ordinary durations of time, such as 1/100th to 1/10th second, increases much with rise of temperature, but when measured for short periods, such as $1/10^6$ second, it does not sensibly increase. The difference is shown to be due to the residual charge which comes out between 1/50,000th second and 1/100th second. The capacity of ice when measured for periods of 1/100th to 1/10th second increases both with rise of temperature and with increase of time; its value is of the order of 80, but when measured for periods such as $1/10^6$ second, its value is less than 3. The difference again is due to residual charge coming out during short times. In the case of glass, conductivity has been observed at fairly high temperatures and after short times of electrification; it is found that the conductivity after 1/50,000th second electrification is much greater than after 1/10,000th, but for longer times is sensibly constant. Thus a continuity is shown between the conduction in dielectrics which exhibit residual charge and deviation from Maxwell's law and ordinary electrolytes.

February 4.—"On the Gases enclosed in Crystalline Rocks and Minerals." By Prof. W. A. Tilden, F.R.S.

From the time of Sir Humphry Davy it has been known that many minerals contain gases as well as liquids enclosed in cavities, which are often large enough to be visible to the unaided eye. The liquid sometimes consists of water or saline solutions, occasionally of mineral naphtha, and not unfrequently of carbon dioxide, which is recognisable by its great expansibility and total disappearance when the temperature is raised to about 31° C.

The presence of gases other than nitrogen and carbon dioxide in natural crystals had not been observed, save in one or two isolated cases, until two years ago, when helium was discovered in certain minerals by Ramsay.

In the course of experiments undertaken with the object of ascertaining, if possible, the condition in which this element, remarkable for its chemical inactivity, is contained in these minerals, I was led to the observation that granite when heated in a vacuum gives off several times its volume of gas, which is combustible, and which consists largely of hydrogen and carbonic oxide. I now find that these two gases are contained, more or less abundantly, in all the crystalline rocks, and, together with carbon dioxide and small quantities of nitrogen and marsh gas, are apparently enclosed in fine cavities which permeate the crystals of quartz, felspar, and other mineral constituents.

Of twenty different rocks examined—granite, gneiss, gabbro, schist, or basalt of different geological ages and from widely different localities—all yielded gas in which hydrogen is present, and is usually the preponderant ingredient of the mixture. The total bulk of the gases extracted, varied from a volume equal to 1·3 times the volume of the rock to 17·8 times its volume. Lava also gave gas, though in smaller quantity, and this also contained hydrogen. Graphite, quartz, beryl and tinstone, as examples of definite minerals associated with the older rocks, gave a similar result.

To account for the large proportion of hydrogen and carbonic oxide in these gases, we must suppose that the rock enclosing them was crystallised in an atmosphere rich in carbon dioxide and steam, at the same time in contact with some easily oxidisable substance, probably a metal or metallic carbide, at a moderately high temperature. No free oxygen has been found in any

of these gases, neither has helium been detected. This latter substance seems to be confined to minerals which contain the heavy metals, such as uranium and thorium, and at present it has not been found in any simple silicate.

Physical Society, February 12.—Special General Meeting.—The chair was taken by Captain Abney, who, as retiring President, referred to some of the changes which had occurred in the Society during the past year. The annual subscription had been raised, but a satisfactory number of new Fellows had been enrolled. The Society had lost two by death. A good deal of work had been done in the direction suggested by the discoveries of Röntgen.—The Treasurer, Dr. Atkinson, then presented his report and balance-sheet for the year 1896. There was evidence of improvement in the financial position, but there was still a deficiency to be met. Profits from sales of publications had been small; it was desirable to reduce the price of the volumes of "Collected Papers of Joule and Wheatstone," and to call the attention of physicists to these valuable records of classical work. Mr. Walker suggested that physical laboratories, especially those in London, should be visited by Fellows of the Society, with a view to comparing notes as to the construction of apparatus; professors of colleges and other institutions should be invited to appoint visiting days for this purpose.—Votes of thanks were passed to the retiring President, Council, and Officers, and also to the Council of the Chemical Society for the use of their rooms at Burlington House.—In replying, Captain Abney said that the coming year would probably bring about further improvements in the system of abstracting and indexing, by co-operation with other Societies at home and abroad. He then read the list of Council and Officers for the year 1897–8. President, Shelford Bidwell, F.R.S.; Vice-Presidents who have filled the office of President: Dr. Gladstone, Prof. G. C. Foster, Prof. Adams, The Lord Kelvin, Prof. Clifton, Prof. Reinold, Prof. Ayrton, Prof. Fitzgerald, Prof. Rücker, Captain Abney. Vice-Presidents, Major-General E. R. Festing, L. Fletcher, Prof. Perry, G. Johnstone Stoney. Secretaries: T. H. Blakesley, H. M. Elder. Foreign Secretary (new office), Prof. S. P. Thompson. Treasurer, Dr. Atkinson. Librarian, C. Vernon Boys. Other members of Council: Walter Baily, L. Clark, A. H. Fison, Prof. Fleming, R. T. Glazebrook, Prof. A. Gray, G. Griffith, Prof. Minchin, Prof. Ramsay, J. Walker. The newly-elected President, Mr. Shelford Bidwell, then took the chair, and an ordinary meeting was held. Mr. Blakesley read a paper by Mr. H. H. Hoffert, "On the use of very small mirrors with paraffin lamp and scale." For the mirrors of reflecting instruments the author prefers small rectangular strips of microscope cover-glass, chosen thin and plane. These are first silvered and then cut to shape by a splinter of diamond embedded in wax. They are about 8 mm. long, by 1·5 mm. broad, and are suspended so that their longest sides are vertical. Rectangular mirrors suspended in this way are lighter, and have less inertia than round mirrors of equal aperture. A paraffin-lamp flame placed edgewise to the mirror gives sufficient illumination. The image of the flame is focussed on the mirror by a lens midway between them, it is a right, vertical line, and thus conforms to the shape of the mirror. A scale is fixed upon a screen between the lens and lamp; and the screen has a circular aperture just below the centre of the scale, provided with a vertical cross-wire. The relative position of screen and lens is adjusted so that an image of the wire is formed upon the scale after reflection at the mirror. Mr. Boys said he had frequently used small mirrors constructed as described by the author, and he could not see what was new in the method, except that a paraffin lamp had been found sufficiently bright for the purpose. It is desirable to diminish inertia by choosing extremely thin glass. Microscope cover-glasses are generally supplied in squares or discs very fairly equal in size; if they are dealt out on a table like a pack of cards, their relative thickness can be judged by the note produced as they fall. Flatness can be estimated nearly enough by balancing them one by one upon the knuckle nearly level with the eye, and observing the reflection of an illuminated straight edge, such as a window bar. All rejected glasses should be broken. The good ones can be further examined by a telescope and artificial star. A common "writing" diamond is best for cutting the thin plates. Special care must be taken not to distort the mirror in fixing to the suspended system. If liquid shellac is used in the attachment, distortion will certainly occur, at any rate if it is applied throughout the whole length of the mirror. The best way is to make the attachment at a mere point, near the top of the mirror; using a speck of shellac as viscous as possible, and heating, if necessary, by radiation, not by conduction. Mr. Boys thought that a reflecting prism near the mirror might be used in certain cases where a paraffin lamp with its inevitable vertical flame was required for horizontal projections. For general purposes, Mr. Boys prefers some such arrangement as the following: If the source of light is a point, a lens is employed, forming an image of the source upon the mirror. (If the source of light is a surface, this lens is evidently superfluous.) The cross-wire is stretched near to the lens on the side towards the mirror. It is now necessary to focus the cross-wire upon the scale, and this is best done by a plano-convex lens fixed as near as possible to the mirror, with its plane face towards the mirror. The light passes twice through this lens. As it may be necessary to change the plano-convex lens from time to time, according to the distance of the scale, Mr. Boys attaches it with a little vaseline to a strip of plate glass in front of the instrument. One advantage of such an optical system is that it allows the instrument to be set up in the same position, with respect to the scale, at all times. Dr. Thompson pointed out that Mr. Hoffert had obtained his results using only *one* lens, by properly choosing the position of the cross-wire.—A vote of thanks was given to the author, and the meeting adjourned until February 26.

Entomological Society, February 3.—Mr. Roland Trimen, F.R.S., President, in the chair.—Mr. F. Bates, Mr. D. D'A. Wright, and Mrs. E. Brightwen were elected Fellows of the Society.—Mr. Champion exhibited an extensive series of Coleoptera collected by Mr. R. W. Lloyd and himself in the Austrian Tyrol, and containing about 450 species, including 35 of Longicornia, and about 20 of Otiorrhynchus. He also exhibited about 85 species of Coleoptera from Cintra, Portugal, collected by Colonel Yerbury, the most interesting of these being *Carabus lusitanicus*, F.; also two specimens of the rare *Zeugophora flavicollis*, Marsh., from Colchester. Mr. Tutt showed, for Mr. W. H. B. Fletcher, typical *Zygaena ochsenheimeri*, Zell., from Piedmont, and hybrids between a female of that species and *Z. filipendulæ*. The progeny was fertile *inter se*, the males closely approaching *Z. ochsenheimeri*, the females *Z. filipendulæ* in character. He also exhibited, for Mr. J. B. Hodgkinson, a number of obscure British Microlepidoptera, some of which had been described as new species. The determinations were criticised by Lord Walsingham, Mr. Bower and Mr. Barrett, and the former speaker strongly deprecated the practice of positively recognising or describing obscure species from single or worn specimens, particularly when British.—Mr. Barrett showed specimens of the true *Platyptilia tesseradactyla*, L. (= *P. fischeri*, Zell.) new to the United Kingdom, and taken in Co. Galway.—Mr. McLachlan exhibited cooked locusts (*Schistocerca peregrina*) sold in the market of Biskra, Algeria, and received from the Rev. A. E. Eaton. They were cooked whole, but the abdomen only was eaten. The President, Mr. Barrett, and Mr. Blandford made some remarks on the subject.—A paper was communicated by Dr. A. G. Butler, on "Seasonal dimorphism in African butterflies," which led to a long discussion, chiefly on the so-called "dry-season" and "wet-season forms." Mr. Merrifield stated that he had been unable experimentally to modify the colour and markings of Lepidoptera by variations in humidity. Mr. Tutt believed that Mr. Doherty had obtained "wet season forms" of Oriental species by keeping the pupæ in a moist atmosphere.

EDINBURGH.

Royal Society, February 1.—Lord Kelvin in the chair.—A paper by Dr. J. Clarence Webster, on the changes in the mucosa of the corpus uteri, and in the attached fœtal membranes during pregnancy, was laid on the table. Prof. D'Arcy Thompson described a very simple logical machine.—A paper by Lord Kelvin, Dr. Beattie and Dr. Smolan, on the conductive quality induced in air by Röntgen rays and by violet light, was read. (See page 343.)—Lord Kelvin read a paper on crystallisation according to rule. For example, as the beginning of a crystal forming from molecules moving freely in a solution consider a cluster of 13 balls, one touched by 12 neighbours around it (model shown). This presents 8 triangular beds and 6 square ones, on which a wandering molecule may lie down. Let a rule be that a wandering molecule takes the first square bed which comes in its way, but never takes a triangular bed if

a square one is vacant. The 6 square beds thus become occupied, and an octahedron of 19 balls is formed, each plane face of which is an equilateral triangle of 6 balls with 3 in each edge. Each triangular face presents 4 triangular beds, of which the middle one is shallow, and the 3 around it deep (tried with a probe pin). There being now no square beds, wandering molecules take triangular beds; but the rule (to make the whole assemblage homogeneous and equilateral) must be that only deep triangular beds are eligible. Thus procedure according to rule adds 24 balls, and we have a cluster of 43 balls (model shown), which presents 2 kinds of triangular or 3-contact beds and 12 equal and similar 5-contact beds, but no square beds. The 12 5-contact beds are next to be filled. These give us a cluster of 55 balls (model shown), presenting 6 square faces of 9 balls, with 4 square beds, and 8 triangular faces of 6 balls each. The 24 square beds are next to be filled, and we have a cluster of 79 balls presenting 6 square beds. The next action, according to rule, fills these, and gives us a regular octahedron of 85 balls, with 15 balls in each face and 5 in each edge. Each triangular face contains 16 triangular beds, of which 10 are deep and 6 shallow. To continue the crystallisation, we may suppose all the deep triangular beds equally eligible; and any one of them may be taken by a molecule deposited from the solution, and any one of the 6 equal and similar 4-contact beds between it and neighbours may be taken next. We shall never find any 6-, 7-, 8-, or 9-contact beds formed if the following rule is rigorously observed in continuing the crystallisation. Five-contact beds must be occupied when any are vacant. When none of these remain, 4-contact beds must be occupied, and whenever no 5-contact or 4-contact beds remain, we shall find that we have a regular octahedron. To continue the crystallisation, any one of the deep triangular beds may be taken by a wandering molecule, and the process continued rigorously according to rule. The formation of garnet (rhombic dodekahedron) was illustrated on similar principles by cubic molecules cohering by attractions between "corners" and relatively oriented by quasi-repulsions between edges. Definite laws of force between molecules are suggested, according to which an ideal "complete" crystal of anorthic system, or of any system possessing symmetry, would be a figure of minimum potential energy, and would be of perfectly determinate figure. The number of such configurations would be infinite if the number of molecules were infinite; but practically for a crystal in nature the number that could probably occur might be hundreds, or might be only one. And *the* one configuration of absolutely least potential energy would be a perfect crystal of unique quality.

PARIS.

Academy of Sciences, February 8.—M. A. Chatin in the chair.—On fictitious waterspouts, by M. H. Faye. It is contended that the name of waterspout (*trombe*) has been given to two quite distinct phenomena solely on account of their external resemblance. The true waterspout is in rapid rotation destroying whatever it touches, has a definite direction, moves with a high velocity, has no aspirating power, and comes from above. The false waterspout is distinguished by having a small and uncertain rotation, no definite course, aspirating and ascending movement, and also by the fact that its source of motion is at its base, on the earth.—New researches on the estimation of pyrophosphoric acid, by MM. Berthelot and G. André. The pyrophosphate is precipitated as the magnesium salt by a mixture of magnesium chloride, ammonium acetate and chloride, in the presence of a large excess of acetic acid. The precipitate thus obtained is of complex composition containing sodium and ammonium in addition to magnesium. The composition of the precipitate, moreover, appears to depend upon the amount of washing it has received.—Some historical remarks on metaphosphoric acid, by MM. Berthelot and G. André.—The reduction of nitrates in arable earth, by M. P. P. Dehérain. As the result of the study of the destruction of nitrates in aqueous solutions by denitrifying organisms present in manure, it is shown that the treatment of farm manure with dilute sulphuric acid, previously recommended as a means of destroying denitrifying organisms, is not only expensive, but is, moreover, useless and harmful.—Results of the solar observations made at the Royal Observatory of the Roman College during the second half of 1896, by M. P. Tacchini.—On the zeros of certain analytical functions, by M. Desaint.—On the comparison of the times of oscillation of two pendulums of very nearly the same period, by M. G. Bigourdan. A modification of the arrangement described by M. Lippmann, in which the pendulum clock is replaced by a chronometer, and in which no electrical apparatus is required.—On a new measurement of the coefficient of viscosity of air, by MM. Ch. Fabry and A. Perot. In the absolute electrometer, described a short time ago, equilibrium was found to be only very slowly attained when the distance between the plates was very small (below 75 μ), on account of the viscosity of the air between the plates. The experimental study of the motion produced by the addition of a small surplus charge on the centre of the moving plate has led to a new determination of the coefficient of viscosity of air, $1{\cdot}73 \times 10^{-4}$ at 13° C.—Study of the variations of energy, by M. Vaschy.—On the principle of Avogadro-Ampère, considered as a limited law, by M. A. Leduc.—On the ammoniacal chlorides of silver, by M. R. Jarry. It is shown that solutions of silver chloride in ammonia contain the definite compounds $AgCl.3NH_3$ and $2AgCl.3NH_3$, and the dissociation pressure of the ammonia is the same in aqueous solution as in a vacuum.—On some colour reactions, by M. E. Pinerua. Some colour reactions obtained by the use of β-naphthol-sulphonic-acid. Tartaric, citric, malic, and nitrous acids give characteristic reactions.—On a new method of preparing primary amines, by M. Marcel Delépine. The alkyl chloride, bromide, or iodide is combined with hexamethylene amine, in presence of chloroform, and the product hydrolysed with aqueous hydrogen chloride.—Improvements in the match industry, with especial reference to the health of the operatives, by M. Magitot. The ameliorative measures proposed depend upon a good artificial ventilation, and a careful selection of the operatives, especial stress being laid on the necessity of the latter having no unsound teeth.—On the estimation of potassium bitartrate in wines, by M. Henri Gautier.—On the essence of basil, by MM. Dupont and Guerlain.—The argon and nitrogen in the blood, by MM. P. Regnard and Th. Schlœsing. The gases obtained from a litre of blood gave 20·4 cc. of argon and nitrogen, 0·42 cc. of which was argon.—On the colours of irradiation in short luminous impressions, by M. Aug. Charpentier.—On a new method of electrification, by M. Charles Henry.—Research on the evolution of the *Urnes*, by MM. J. Kunstler and A. Gruvel.—On the gum disease of the cocoa plant, by M. Louis Mangin.—On an apparatus for measuring the refractive indices of minerals in rocks, by M. Fred Wallerant.—On the granite of Pelvoux, by M. P. Termier.—Generalisation of a formula in probabilities, by M. C. Maze.

SYDNEY.

Royal Society of New South Wales, December 2, 1896.—Mr. J. H. Maiden, President, in the chair.—On the presence of a true manna on a "blue grass," *Andropogon annutatus*, Forsk., from Queensland, by R. T. Baker and Henry G. Smith. The substance is found on the nodes of the stems in masses as large as marbles. This appears to be the first time that a substance of this character has ever been described from a grass. Not only is the grass indigenous in Australia, but occurs in tropical Asia and Africa. The manna is sweet, and nearly three parts of it consists of the substance mannite, which, although sweet, is not a sugar. Besides the presence of this interesting substance, a peculiar ferment was discovered in the manna, which apparently has the power to decompose cane-sugar without the evolution of carbonic acid or gases of any kind. It probably belongs to the Saccharomycetes, and is allied to the ferments of which the yeast plant is a type. It has been isolated from the manna, and was shown at the Society working in a solution of cane-sugar, and also under the microscope. The investigations are not yet completed; but, so far, it appears to be probably the cause of the occurrence of the mannite in the manna, and not only has it the power to alter cane-sugar to mannite, but, with the assistance of yeast, to decompose mannite also—a fact of no little interest.—Remarkable hailstorm of November 17, 1896, in parts of parish of Gordon, by E. du Faur—On the determination of the meridian line by solar observations with any altazimuth instrument, by G. H. Knibbs. The paper dealt with the rigorous mathematical theory of the subject; tables and formulæ, for facilitating the reducing of this class of observations with precision, were supplied. The astronomical conditions of good results were fully dealt with, the matter being of considerable importance in practical geodesy.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 18.

ROYAL SOCIETY, at 4.30.—On the Iron Lines present in the Hottest Stars (Preliminary Note): J. N. Lockyer, F.R.S.—On the Significance of Bravais' Formulæ for Regression, &c., in the case of Skew Variation: G. U. Yule.—Mathematical Contributions to the Theory of Evolution. On a Form of Spurious Correlation which may arise when Indices are used in the Measurement of Organs: Prof. K. Pearson, F.R.S.—Note to the Memoir of Prof. Karl Pearson, F.R.S., on Spurious Correlation: F. Galton, F.R.S.

ROYAL INSTITUTION, at 3.—Problems of Arctic Geology: Dr. J. W. Gregory.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

LINNEAN SOCIETY, at 8.—On certain Points in the Anatomy and Morphology of the Nymphæaceæ: D. T. Gwynne Vaughan.—The Adhesive Discs of Ercilla spicata, Uog.: T. H. Burrage.

CHEMICAL SOCIETY, at 8.—The Oxidation of Sulphurous Acid by Potassium Permanganate: T. S. Dymond and F. Hughes.—Sodamide and some of its Substitution Derivatives; also Rubidamide: Dr. A. W. Titherley.

CAMERA CLUB, at 8.15. Practical Use of X-Rays: Sydney Rowland.

FRIDAY, FEBRUARY 19.

ROYAL INSTITUTION, at 9.—The Approaching Return of the Great Swarm of November Meteors: Dr. G. Johnstone Stoney, F.R.S.

GEOLOGICAL SOCIETY, at 3.—Annual Meeting.

EPIDEMIOLOGICAL SOCIETY, at 8.

SATURDAY, FEBRUARY 20.

ROYAL INSTITUTION, at 3.—Growth of the Mediterranean Route to the East: W. F. Lord.

MONDAY, FEBRUARY 22.

SOCIETY OF ARTS, at 8.—The Industrial Uses of Cellulose: C. F. Cross.

IMPERIAL INSTITUTE, at 8.30.—The Past, Present, and Future Sugar Supply of the British Empire: C. A. Barber.

SANITARY INSTITUTE, at 8.—Law relating to the Supervision of Food Supply: A. Wynter Blyth.

INSTITUTE OF ACTUARIES, at 7.—Governmental Supervision of Life Insurance in the United States of America: Sheppard Homans.

CAMERA CLUB, at 8.15.—Spitzbergen: E. T. Garwood.

TUESDAY, FEBRUARY 23.

ROYAL INSTITUTION, at 3.—Animal Electricity: Prof. A. D. Waller, F.R.S.

ANTHROPOLOGICAL INSTITUTE, at 8.30.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Main Drainage of London: J. E. Worth and W. Santo Crimp.—The Purification of the Thames: W. J. Dibdin.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—The *f*/6 Stigmatic Lens and the New Astigmatic Corrector: Thomas R. Dallmeyer.—The Perfected Krömskóp: H. E. Ives.

ROYAL VICTORIA HALL, at 8.30.—X- and other Rays of Light: Dr. J. W. Waghorn.

WEDNESDAY, FEBRUARY 24.

SOCIETY OF ARTS, at 8.—Reproduction of Colour by Photographic Methods: Sir Henry Trueman Wood.

ZOOLOGICAL SOCIETY, at 8.30.—On the Nature and Origin of the Rauenthal Serpentine: Miss Catherine A. Raisin. (Communicated by Prof. T. G. Bonney, F.R.S.)—On Two Boulders of Granite from the Middle Chalk of Betchworth (Surrey): W. P. D. Stebbing.—Coal—A New Explanation of its Formation, or the Phenomena of a New Fossil Plant considered with reference to the Origin, Composition, and Formation of Coal Beds: W. S. Gresley.

THURSDAY, FEBRUARY 25.

ROYAL SOCIETY, at 4.30.—The following Papers will *probably* be read:—Note on the Dielectric Constant of Ice and Alcohol at very Low Temperatures: Prof. Dewar, F.R.S., and Prof. Fleming, F.R.S.—On the Relation between Magnetic Stress and Magnetic Deformation in Nickel: Dr. E. T. Jones.—On the Relations between the Cerebellar and other Centres (namely, Cerebral and Spinal), with especial reference to the Action of Antagonistic Muscles (Preliminary Account): Dr. Max Löwenthal and Prof. Horsley, F.R.S.—On the Action of Light on Diastase, and its Biological Significance: Prof J. R. Green, F.R.S.—Fragmentation in *Linens gesserensis*: A. Brown.

ROYAL INSTITUTION, at 3.—The Problems of Arctic Geology: Dr. J. W. Gregory.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Electric Interlocking the Block and Mechanical Signals on Railways: Reply of F. T. Hollins to the Discussion.—Relative Size, Weight, and Price of Dynamo-electric Machines: E. Wilson.

SANITARY INSTITUTE, at 8.—Sanitary Laws and Regulations governing the Metropolis: A. Wynter Blyth.

CAMERA CLUB, at 8.15.—Silchester, the Result of Recent Explorations: H. Jones.

FRIDAY, FEBRUARY 26.

ROYAL INSTITUTION, at 9.—Palestine Exploration: Lieut.-Colonel C. R. Conder.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Rockers and Expansion-Bearings as applied to Girders of Short Span: A. F. Baynham and F. B. H. Debree.

SATURDAY, FEBRUARY 27.

ROYAL INSTITUTION, at 3.—The Growth of the Mediterranean Route to the East: W. Frewen Lord.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—On Human Nature: A. Schopenhauer, selected and translated by T. B. Saunders (Sonnenschein).—Elements of Theoretical Physics: Dr. C. Christiansen, translated by Prof. W. F. Magie (Macmillan).—Zeit-und Streitfragen der Biologie: Dr. O. Hertwig, Heft 2 (Jena, Fischer).—Beiträge zur Kenntnis der Septalnecttarien: J. Schniewind-Thies (Jena, Fischer. Beiträge zur Lehre von der Fortpflanzung der Gewächse: Dr. M. Möbius (Jena, Fischer)—Kainogenesis als Ausdruck differenter Phylogenetischer Energien: Dr. E. Mehnert (Jena, Fischer).—Das Botanische Practicum: Dr. E. Strasburger, Dritte Umgearbeitete Auflage (Jena, Fischer).—Wasted Records of Disease: C. E. Paget (Arnold).—Farthest North: Dr. F. Nansen, 2 Vols. (Constable).—Physics, an Elementary Text-Book for University Classes: Dr. C. G. Knott (Chambers).—Handbook for Mechanical Engineers: Prof. H. Adams, 4th edition (Spon).—Recueil de Procédés de Dosage: Prof. G. Arth (Paris, Carré).—Massachusetts Institute of Technology, Boston, Annual Catalogue, 1896–97 (Cambridge, Mass.).—Report of the Commissioner of Education for the Year 1894–5, 2 Vols. (Washington).

PAMPHLETS.—Photography as a Hobby: M. Surface (Lund).—Geological Literature added to the Geological Society's Library during the Year ended December 31, 1896 (Geological Society).—Tabellen für Gasanlysen, &c.: Prof. G. Lunge (Braunschweig, Vieweg).

SERIALS.—Engineering Magazine, February (Tucker).—Quarterly Journal of the Geological Society, Vol. liii. Part 1, No. 209 (Longmans).—General Index to the First Fifty Volumes of the Quarterly Journal of the Geological Society, Part 1 (Longmans).—Bulletin de l'Académie Royale des Sciences, &c., de Belgique, 1896, No. 12 (Bruxelles).—Minnesota Botanical Studies, Bulletin No. 9 (Minneapolis).—Journal of the Franklin Institute, February (Philadelphia).—American Naturalist, February (Philadelphia).

THE NATIONAL PHYSICAL LABORATORY.

THE case for the establishment of a National Physical Laboratory is very simple. The Kew Observatory began in a humble way, but became famous in the last generation for the work done there in connection with terrestrial magnetism. As the President of the Royal Society remarked, in his last annual address, the late Sir William Grove, more than thirty years ago, expressed the hope that Kew might become "an important national establishment." "And if so," he added, "while it will not, I trust, lose its character of a home of untrammelled physical research, it will have superadded some of the functions of the Meteorological Department of the Board of Trade, with a staff of skilful and experienced observers."

In the interval which has elapsed since Grove uttered these words Kew has advanced. It has become a considerable standardising institution. Including a large number of clinical thermometers, about 21,000 instruments are now examined there annually, and in spite of this commercial success, it still maintains its character as a home of physical research.

During the last ten years a similar institution has been established, on a much larger scale, at Charlottenburg. It is needless to describe the Reichsanstalt in these columns. It is sufficient to say that it is divided into two Departments—the one devoted to physical research, the other to technology. The work which the new Institution has done is very good, its reputation stands high, and after full consideration the chief scientific and technical Societies of this country decided to ask the Government to assist in placing Kew in a position to be similarly useful. A Committee was appointed, consisting of representatives of the Royal Society, of the British Association, of the Royal Society of Edinburgh, the Royal Irish Academy, of the Physical, Chemical and Astronomical Societies, and of the Institutions of Civil and Electrical Engineers. A memorial, prepared during the meeting of the British Association at Liverpool, was signed by a large number of representatives of science and industry. The request made to the Government suggested that the grant should be expended partly in improving the work of standardising, partly in promoting researches of a kind which cannot be undertaken by individuals or educational establishments. The terms in which this last request were made were almost a literal translation of those used in the memorandum in which von Helmholtz set forth the aims and objects of the Reichsanstalt. Lord Salisbury, however, entirely declined to accept this part of the programme, though he held out hopes that something might be done to help in the work of standardisation and verification. With this decision we do not quarrel. It is impossible for the Prime Minister to go beyond public opinion in such matters. We hope that the good work done at Kew may receive State aid, but the outburst in the *Times* of Saturday is sufficient to show that the innate tendency of the English people to distrust and reject all opinions based on special or expert knowledge is aroused by the terrible word "research." It is curious to observe in how many ways this tendency displays itself.

The official head of science in this country is a man on whom a peerage has just been conferred for an application of science to surgery by which thousands of lives have been saved. Lord Lister is also the head of an Institute for Preventive Medicine, which, if properly supported, would give to England all the benefits which are to be derived from the most modern methods of contending with infectious disease. The reward that he receives for these further efforts to benefit this curious Anglo-Saxon race is that a monster petition is presented to the Home Secretary against the licensing of the Institute for the performance of vivisection. If, therefore, a Pasteur Institute in London is anathema, we can hardly wonder if the gorge of the average Briton rises at the suggestion that there should be a Reichsanstalt at Kew.

The "splendid isolation," which we prefer to an alliance with either France or Germany, appears to include a rejection of their methods of avoiding rabies and correcting thermometers.

Some measure of the logical weakness of the opposition is, however, afforded by the misrepresentations of the *Times* article. The allegation that the memorandum attributed the loss of trade in thermometers to improvements in verification made abroad, is absolutely incorrect. The assertion that the Reichsanstalt and the proposed institution would be very different, is made in spite of the fact that the published descriptions of the work of the one, and of the proposed work of the other, are almost identical. Absolute ignorance was displayed as to the part which official science has played in the development of improved thermometers. For those who care for the reputation of a great journal, the article was painful reading. But it is needless here to describe or to defend the idea of a National Physical Laboratory, and we prefer to discuss another point on which we are glad to be at one with the *Times*. We agree that Germany beats us in scientific industries, not only because she fosters them, but because the examiner does not loom so large there as in this country.

It is, however, absurd to tell scientific men to remedy this. Who is responsible for the delay in making the University of London other than the mere college of examiners which at present it is? Almost every scientific man in London has done what he can to bring about that desirable consummation. The delay is due to those who claim to represent the views of the average Briton, as represented by the average passman of the University. Who is it that refuses to receive from candidates for scientific appointments in the Civil Service any evidence of scientific ability other than that which can be displayed in an examination? Not the Professors, but the State. It is a common experience of every teacher of advanced students, that he has to advise some member of his class as to whether he should undertake a piece of practical work or prepare for a particular examination. The teacher has no right to play fast and loose with the future of those who have placed their careers in his hands, and, even at the risk of being called a pedagogue, he is too often reluctantly obliged to confess that the future will be better

assured by success in the examination than by investigation. This is no fault of his. It is the fault of those who having once grasped the fact hat ability of a certain kind can be tested, without any suspicion of unfairness, by marks assigned by examiners to candidates whose names they do not know, insist on applying this test, and this test alone, in as many cases as possible, without inquiry as to whether the ability of the examination-room is the kind of ability for which they are in search, or whether other evidence could not be obtained, sifted and allowed to weigh in the final decision. It is the fault of the public, which regards the mystic letters B.A. or B.Sc. as an infallible test of the merits of a schoolmaster, but would not have a notion of the meaning of the words if he were described as the author of a memoir in the *Transactions* of the Royal Society. Nowhere is a more strenuous condemnation of the defects of the examination system found than among scientific investigators who are also examiners in science. It is, of course, impossible to change suddenly a method to which the public assign a value far above that which it deserves; but if teachers of science suggest any mitigation of its severity, they are at once told that they are seeking to fill their class-rooms with candidates for their patronage, and that they are trying to evade the only satisfactory test of the value of their teaching. Under these conditions they are helpless. It is not they, but those whose motives cannot be misrepresented as self-seeking, whose opinions cannot be misrepresented as biassed, who can loosen the fetters which English public opinion binds around the intelligence of English youth, and, unfortunately, the majority of such persons are convinced that the present system is the best.

We have followed the precedent set by the *Times* in passing from the proposal for the establishment of a National Physical Laboratory to the discussion of the examination system, for we agree that the rejection of the scheme for carrying out research in the one, and the general acceptance of the other, are alike indicative of the present temper of the English people on such questions. They do not believe that scientific ability is worth the cost of training and using it. They refuse to supply laboratories for advanced students, such as German students possess. They make the advancement of a middle-class youth depend entirely on his success in examinations. As represented by the London County Council, they appear to think that the best use to which they can put a Huxley, when they are fortunate enough to secure his services, is to set him to lecture to evening students.

They refuse to admit that there are certain conditions which must be fulfilled if the tasks of giving advanced instruction in science, and of advancing science, are to be carried out successfully, and then they turn and rend those who, in spite of these difficulties, have done something to advance both education and learning. Truly, history repeats itself.

"He said, Ye are idle, ye are idle. Go therefore now and work; for there shall no straw be given you, yet shall ye deliver the tale of bricks. And the children of Israel did see that they were in evil case."

RÖNTGEN RAYS AND CONSTITUTION OF GASES.

Röntgen Rays and Phenomena of the Anode and Kathode. By Edward P. Thompson, M.E., C.E.; with a concluding chapter by Prof. William A. Anthony. Pp. xiv + 190. (New York: Van Nostrand. London: Spon.)

The Constitution and Functions of Gases, the Nature of Radiance and the Law of Radiation. By Severinus J. Corrigan. Pp. viii + 127. (St. Paul: Pioneer Press Company, 1895.)

ALTHOUGH it is but a short time since Röntgen published his famous work on the X-rays, the very large number of scientific papers dealing with the subject, which have been published in all parts of the civilised world, makes the labour entailed in the production of a book of this kind very large.

Mr. Thompson, in his book on the X-rays, has endeavoured to give as complete an account as possible, not only of Röntgen's discovery, but of all the phenomena attending the passage of electrification through gases. With a view to make the subject intelligible to the lay mind, a short account is first given of induced currents and the discharge through gases at atmospheric and lower pressures. The author then passes to the consideration of the magnetic effects of the discharge, and the phenomena observed in the very high vacua of the Crookes' tube. A detailed description is given of Lenard's famous researches on the kathode rays, and of Röntgen's discovery of the X-rays and their properties. Considerable space is devoted to experiments dealing with the photographic developments and the use of the Röntgen rays in surgery. In the concluding chapter, Prof. Anthony sums up the results, and gives a short discussion on wave motion, without, however, venturing to suggest any explanation of the real nature and origin of the X-radiation.

A large number of X-ray photographs, or sciagraphs, as they are termed, are scattered throughout the volume, and some dust figures are also shown, a chapter being devoted to the description of them.

The author has adopted the method of dividing the book into numbered paragraphs, each of which is headed by the experiment to be explained, while references to the original publication are in nearly all cases given. The consequence of this is that the chapters consist of a detailed description of a number of experiments which are quite independent of one another; and as no attempt is made to criticise the results, or connect them together in any way, the result is somewhat confusing. The author, in many cases, lacks discrimination as to the relative importance which he assigns to the various experiments, and much of the earlier part of the book, notably the opening chapter, might be omitted with advantage.

The part of the book which deals with the X-rays, and the recent experiments on the subject, is much the best, and great praise is due to the author for the accurate *résumé* which has been given of nearly all recent work; and it is as a collected and condensed account of recent experimental work on the X-rays and allied phenomena that the book will be found most useful.

In "The Constitution and Functions of Gases," by Severinus J. Corrigan, an attempt has been made to advance a new dynamical theory of gases, and to do away with the necessity of a continuous ether for the transmission of radiation through space.

In the ordinary kinetic theory of gases, which has been worked out so fully by Maxwell, Clausius, and others, the molecules of which the gas is composed are conceived to be in continual motion among one another, each molecule moving through a mean free path, while pressure on a surface is due to the continuous bombardment of the molecules. The theory which Mr. Corrigan advances is as strictly dynamical as the ordinarily accepted one, but is based on quite different assumptions. The molecule, instead of being in continual motion to and fro, is at rest, but is made up of a large number of atoms, which revolve in orbits, approximately circular, round the centre of the molecule with enormous velocities.

The atoms themselves are supposed to be "perfectly elastic, incompressible, spherical solids which are arranged primarily in duads or combinations of two, and the atoms of each duad combination are mutually attracted by a force in each atom, which force, like that of gravity, varies inversely as the square of the distance between the members of the duad." These two atoms are endowed with opposite polarity of some kind, probably magnetic, and are analogous to a system of binary stars of equal mass and volume, and their motion is governed by the laws of motion of celestial bodies. The molecule is supposed to be built up of an enormous number of these rapidly rotating magnetic couples with the planes of their orbits in all directions, so that the molecule is a hollow shell of gas, the surface atoms of which are in extremely rapid motion round the centre of the molecule.

The pressure of the gas is assumed to be proportional to the mass of the gas and the angular velocity or vibration frequency of the atom, while a change of pressure alters the diameter of the atomic orbit. In a very rare gas, therefore, the diameter of the atomic orbit is immensely greater than at ordinary atmospheric pressure.

Proceeding on these assumptions, the author certainly makes his theory satisfactorily account for some of the properties of gases. Great stress is laid on the theoretical deduction, from the hypothesis, of a law of radiation of identically the same form as the empirical formula of Dulong and Petit. The value of the constant is also deduced, and this is in complete agreement with the experimental value.

The ether, instead of being the continuous medium demanded by physicists, is supposed to be molecular and discontinuous—practically a gas of excessive tenuity. A large amount of space is devoted to the consideration of a mode of transmission of radiation, from molecule to molecule of the gaseous ether, with the velocity of light; but so many difficult assumptions are made in the course of it, that the explanation, though plausible, is not at all satisfactory. The impulse which the revolving atom receives from contact with a vibrating surface is supposed to be handed on from molecule to molecule with the velocity of light; but it is not clear why an atom of an adjacent molecule should always be in exactly the right position for the transmission of an impulse.

It will be of interest to mention a few of the results which the author deduces from his equations. The number of atoms in the atmospheric molecule is calculated to be about 10^{14}, and the orbital velocity of the atom of air at atmospheric pressure and temperature 500 million miles per second. The number of atoms per cubic centimetre of the gas agrees very nearly with the results deduced by Lord Kelvin and others. The density of the luminiferous ether (air = 1) is about $3 \cdot 10^{-15}$, and the diameter of a molecule of the ether ·002 inches.

As a consequence of the theory the conjugate atoms would be disrupted at an absolute temperature of 6679° Fahrenheit, and the author considers that disruptive electrical discharges, such as from an induction coil or in lightning, do break up the molecules, and it is the recombination of the dissociated atoms which causes the crash of thunder after the lightning flash.

The most unsatisfactory portion of the book is where the author endeavours to explain electrical phenomena, like atmospheric electricity, and natural disturbances, like tornadoes, by his theory of gases. A table of the dimensions and weights of the atoms of the molecules of the air and ether, which are deduced from the equations, is given; while a supplement is added to the book, deducing the same results in a different manner, and various theories are advanced in regard to the solar corona and astrophysics generally.

Though one may not agree with many of the author's assumptions, the fact remains that an interesting dynamical theory has been advanced which accounts for some phenomena not explained by any other theory; and for those who may be interested in speculations in regard to the nature and constitution of the gases and the ether, the book is well worth reading. E. R.

IMPRESSIONS OF OUT-DOOR NATURE.

A Year in the Fields. Selections from the writings of John Burroughs. With illustrations from photographs by Clifton Johnson. Pp. ix + 220. (London: Smith, Elder, and Co., 1896.)

A-Birding on a Bronco. By Florence A. Merriam. Illustrated. Pp. x + 226. (Boston and New York: Houghton, Mifflin, and Co., 1896.)

Summer Days for Winter Evenings. By J. H. Crawford, F.L.S. Illustrations by John Williamson. Pp. ix + 274. (London: John Macqueen, 1896.)

THE highest merit in any book of natural history is that it contains new and valuable information. Such books are often, but by no means inevitably, dry. Mr. A. R. Wallace may be named as one living writer who gives us new and valuable matter in a thoroughly readable form. Without being absolutely original, a book may yet be well worth writing if it contains a good deal of useful information served up in an attractive way. Then we come to the books which are attractive but not useful, and so to the books which are neither one nor the other.

None of the books before us belong to either the

highest or the lowest class. The naturalist may search them through without finding any passage which throws new light upon an important question. Perhaps we may, rather doubtfully, put "A Year in the Fields" among the books that both amuse and instruct. Mr. Burroughs is most agreeable to read, and now and then he tells us something that we are glad to know. But he sacrifices a little too much to the necessity of pleasing, and his books are impressions rather than studies. Miss Merriam and Mr. Crawford definitely belong to the class which amuses and does not instruct.

Mr. Burroughs has now found his public, and needs no lengthy notice at our hands. He writes as one who lives in daily contact with nature, occupying himself with her superficial aspects rather than with her problems. The reader of his books finds many pleasant pages, like the best descriptive passages of good novels, and occasionally a hint of some curious knowledge or reflection. Such a book as that before us (which, it is necessary to note, contains no new essays) is welcome to the naturalist in his less serious moods; it is genuine literature with a strong flavour of the woods and fields. The volume is illustrated by twenty photographs, of which all but one contain the author's figure in some favourite haunt. It is cheerful to think that he has now escaped from the public office, and is entering old age as a fruit-farmer on the Hudson.

Miss Merriam tells in a sprightly way her observations upon live birds in California. The Bronco is an old horse, from whose back she studied the birds with an opera-glass. The book is crowded with details, but they are hardly ever worth remembering; it relies upon its literary qualities, which are good, but not excellent. There are many illustrations, chiefly of nests or birds' heads.

Mr. Crawford's book is even thinner in substance than Miss Merriam's. A facile writer could come home after sitting for an hour in a garden-chair, or sauntering along a lane, and write such sketches as these almost without effort. They incline to the sermon in some places, to the novel in others. The very best remark in the book, from the naturalist's point of view, is this (p. 100): "The feet [of the lark] are adapted for running. They cover so many of the grass stems at once, that not only does the bird get along very much as one does on snow-shoes, but the elasticity of the pressed-down herbage aids in the spring." The illustrations have no natural history value. L. C. M.

OUR BOOK SHELF.

Guide pour le Soufflage du Verre. By Prof. H. Ebert. Translated from the second German edition, with notes by Prof. P. Lugol. Pp. 191. (Paris: Gauthier-Villars et Fils, 1897.)

THE utility and importance of even a small amount of knowledge in the art of blowing glass is perhaps best known to those who work in chemical, physical, and astrophysical laboratories. Tubes will crack, pumps will get broken, and many other similar mishaps will occur in the ordinary course of laboratory work. In such cases two remedies are available: either new apparatus must be bought, or it must be made. The former is doubtless the easiest, but the most expensive; while the latter is, in many cases, a saving of both time and money.

In England, Mr. Shenstone's little book on the methods of glass-blowing is the one which is most generally used. Prof. Ebert practically based his first edition on this admirable little treatise, embodying in it both his own observations and methods and those of others. The second edition, however, was considerably altered; in fact the book was practically reconstructed, as it was his intention to insert results of more recent experience, and give a strictly systematic course on glass-blowing.

The book before us is a French translation of this second edition, and it will be found to give full details to its readers how to make all the more common glass apparatus in use in laboratories, and how to mend those when broken. Prof. Ebert has adopted a logical sequence of the chapters, leading the glass-blower gradually by easy stages to the more difficult operations. The reader is first made to understand the mysteries of the blow-pipe itself. He is next given exercises which involve the training of the hands, first singly and then together. More difficult exercises are then put before him, from the construction of a trap to some complicated forms of vacuum tubes. In each lesson the necessary steps are clearly described, and in many cases illustrations are given showing the appearance of the apparatus at its several stages. This is an important point, for the great difficulty that a beginner meets with at first is not so much the actual making of the apparatus (which is acquired after a little practice), but a lack of knowledge of the various steps that have to be accomplished before the final stage is reached. For example, to make a large bulb in the middle of a tube, the beginner generally tries to blow the bulb directly without adopting the more easy stages of blowing three small bulbs close together, and amalgamating them into one large one.

The appendix contains some additional information which will be found useful to those working with glass, such as engraving on glass, the graduation of tubes, &c. Some further notes have also been added by the translator.

As a treatise on glass-blowing, Prof. Ebert's book can be thoroughly recommended, and those who are unable to master the German edition will find Prof. Lugol's translation an admirable substitute. W. J. S. L.

Projectiles de Campagne de Siège et de Place: Fusées. By E. Vallier. Pp. 178. (Paris: Gauthier-Villars.)

L'Éclairage. Éclairage aux gaz, aux huiles, aux acides, gras, &c. By Prof. Julien Lefèvre. Pp. 180. (Same publishers.)

Les Succédanés du Chiffon en Papeterie. By V. Urbain. Pp. 179. (Same publishers.)

THESE three volumes belong to the very practical series published under the editorship of M. Léauté, as the Encyclopédie scientifique des Aide-Mémoire.

M. Vallier confines himself to dealing with the projectiles from large guns. The first part of the book is concerned with field artillery (*projectiles de campagne*); the second with ordinary cast shells, shrapnels, and explosive shells (*projectiles de siège et de place*), and the third with fuses arranged to explode when the projectile collides, or at a given point of the trajectory. The volume is full of instructive information on the manufacture, properties, and mode of employment of different types of projectiles used in ordnance pieces.

In "L'Eclairage," Prof. Lefèvre first describes the principles of various systems of illumination, excluding electric lighting. He deals with the many processes involved in the production of gas from coal, and shows how gas is distributed. The many methods employed to burn gas most effectively are also described. Lighting by special gases, and by acetylene, form the subject of two other chapters. In a similar way lighting with candles,

vegetable oils, and mineral oils are dealt with, the processes of manufacture and purification, and the various kinds of lamps being described. A brief comparative statement of the prices and efficiency of different systems of lighting concludes the book.

The cellular substance of plants now used in the manufacture of paper, are known collectively as *succédannés des chiffons*. M. Urbain describes the different kinds of straw, Sparta grass, and wood used for this purpose; the physical and chemical constitution, so far as it is known, of cellulose; the manufacture of pulp from different cellular substances; and the methods of bleaching the paper. His book should be of use in showing how the structural elements of plants are now utilised in paper manufacture.

Alterations of Personality. By Alfred Binet. Translated by Helen Green Baldwin; with notes and a preface by Prof. J. Mark Baldwin. Pp. xii + 356. (London: Chapman and Hall, Ltd., 1896.)

M. BINET'S volume originally appeared in the "Bibliothèque Scientifique Internationale," and was reviewed in NATURE in July 1892 (vol. xlvi. p. 219). The subject with which it deals is beset with peculiar difficulties, and great caution is necessary before coming to any definite conclusions concerning the psychological phenomena involved; for though many observers have recorded strange alterations and modifications of personality, the cause of this spontaneous somnambulism is much disputed. M. Binet holds "that in a great many cases, and in very diverse conditions, the normal unity of consciousness is broken up, and several distinct consciousnesses are formed, each of which may have its own system of perceptions, its own memory, and even its own moral character." His book contains a detailed account of the results of researches by various psychologists on these alterations of personality. It is an authoritative statement of facts, and the translation, with Prof. Baldwin's notes, will be read with interest by the more intelligent section of the general public, as well as by the student of psychology.

The Hemiptera-Homoptera of the British Islands. By James Edwards, F.E.S. Pp. vi + 271. (London: L. Reeve and Co., 1896.)

STUDENTS of the insects of the Homopterous sub-order of the Hemiptera will find this volume very serviceable in the determination of their captures. The work is a descriptive catalogue of the families, genera, and species of the Cicadina and Psyllina indigenous to Great Britain and Ireland, with notes as to localities, habitats, &c. Particular attention is given to the consideration of characters which are of the greatest service in determining the several species and larger divisions of the insects described.

Analytical Keys to the Genera and Species of North American Mosses. By C. R. Barnes. Revised and extended by F. D. Heald. (Madison, Wis.: published by the University, 1897.)

ALTHOUGH a revision and extension of previous works by the same author, this is an important and valuable addition to the literature of bryology. It consists in the first place of a key to all the genera of Musci, including Sphagnaceæ, found in North America, and secondly of a similar key to all the species in each genus. Some idea of the labour involved will be gathered when it is stated that the genera number over 140; and that in some of the genera—*e.g. Sphagnum, Orthotrichum, Bryum, Hypnum*—there are from 50 to over 90 species. In a copious appendix is given a diagnosis of all the new species described between 1884 and 1896.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dynamical Units.

MANY of the writers of letters on this subject seem to have forgotten that the question Prof. Perry raised was as to the best system of units to use with a class of *engineering students*. This question is very seriously complicated by the fact that all their books, and almost all their teachers, use a system of units which is *not* that of the poundal, but is essentially the one that Prof. Perry advocates. This is a very serious fact that every teacher of engineering students must take account of, and the question is, "What system shall the teacher use with engineering classes?" I entirely agree with Prof. Perry in thinking that it is much better for the teacher to accommodate himself to the requirements of his class than for him to force his class to use one system when working for him, and another outside his classrooms. This latter plan tends to perpetuate the prevalent notion that science has nothing to do with practice.

As regards the question of why students find dynamics and the notion of mass in particular so difficult, I do not believe that this is due to any difficulties about various systems of units. In matters upon which their ideas are clear and distinct, such as length and time, the existence of different units, feet, yards, miles, &c., minutes, days, &c., presents very little difficulty. To British students these varieties of units in which to measure the same quantity are so familiar, that they naturally look upon varieties of units with contempt. It is only when the thing measured is not clearly and distinctly conceived, that confusion and all sorts of difficulties arise. Hence the importance of getting students actually to come into contact with the things themselves. Until a student has some ideas of density, acceleration, &c., as things to be measured, he will be quite certain to misapply the rules he has learnt for dealing with the black marks he makes on a piece of paper, and which he calls by their names. Now of all these dynamical quantities, of which students are generally expected to form clear and distinct ideas without any actual experience of the things themselves, the most abstruse, and the one about which the most metaphysical statements are made, is "quantity of matter" or "mass." *A priori*, there is no way by which we can determine whether a quantity of gold is equal to a quantity of iron. In ordinary practice there are two kinds of equality which are commonly used: volume and weight. If I tell any ordinary man to mix equal quantities of whisky and water, he will mix equal volumes. It is quite as common to mean equal volumes as equal weights by equal quantities in common language. When a student is told, as an *explanation* of the word "mass," that it means "quantity of matter," there is an appeal made from the obscure to the more obscure. It is a case of huggermugger. The student thinks the teacher must have some clear and distinct idea of what he means by "quantity of matter," and is ashamed to say that to him it is no explanation of mass to call it "quantity of matter." Thus begins the demoralisation of the student. He is demoralised by having to swallow undigested a term of which neither he nor his teacher has a clear and distinct idea, and he naturally concludes that the whole subject is one that "no fellow can understand."

If teachers and books would give up this metaphysical notion of "quantity of matter," and would deign to confine their attentions to actually measurable quantities, like volume, weight, and inertia, the student could be given, by making experiments, clear and distinct ideas of these properties of matter as actual quantities to be measured. Once he had these clear and distinct ideas, a variety of units for measuring each of them would not present any serious difficulty. That the inertia of matter is proportional to its weight, that the inertia of a body is the same here as in the moon and Jupiter—these are most important physical facts to be proved by experiment, because we have no other way of ascertaining them. It is often *assumed* that the inertia of a hot body is the same as of the same body when cold; but I do not know of any accurate experiments having ever been made to prove it, and I am quite certain that a great deal too little is known of the structure of matter, and of its relations with the ether, to be able to prove *à priori* that the inertias are the same. The suggestion would probably involve the further suggestion

that we could make a machine to utilise some of the energy in the ether; but does any one profess to know so much of that remarkable thing as to be quite certain that this is impossible? Any way, there is no doubt that to a considerable degree of accuracy inertia *is* a constant property of a body, and equal inertias may consequently be very reasonably considered as equality of such a very important property of two bodies, that scientific people are justified in their shortly describing the bodies as equal, which is what they usually do, and is all that they can really mean when they speak of equal quantities of iron and gold. Why, then, trouble unfortunate students with the idea that there is some huggermugger metaphysical "quantity of matter" called "mass," of which they are supposed to have a clear and definite conception distinct from this equality of inertia? Why not call it inertia when it is inertia that is meant, and drop out of use that word "mass," round which such a tissue of indistinct and obscure ideas have grown, that it is almost hopeless to separate it from them.

I hope some word more euphonious than "slug" will be found for the unit of inertia on the engineer's system. I would suggest "ert" as a term that would easily recall the quantity inertia. GEO. FRAS. FITZGERALD.

Trinity College, Dublin, February 10.

The Flight of Gulls in the Wake of Steamers.

MANY persons have remarked the extraordinary power displayed by gulls of keeping pace with a steamer without any motion of their wings. A few days ago, I had a good opportunity of observing this during a voyage from Alexandria to Marseilles.

When the wind was blowing at right angles to the course of the vessel, having first gained some slight elevation, the gulls would glide downwards with expanded wings, making, during the descent, rapid progress in the same direction as the steamer. When quite near the water they would suddenly turn and face the wind, at the same time giving their bodies an upward incline, and the wind would lift them to their former elevation, after which the process would begin again. A wind blowing horizontally has the power of lifting, only because each stratum, so to speak, of air moves more rapidly than the stratum immediately below it. Consequently, as the bird rises, it has the inertia due to the fact that it has just emerged from the slower current below. Thus it may be compared to a kite, the inertia taking the place of the string. When gulls progress in this way, at right angles to the wind, the vessel does not in any way assist them, and, occasionally, when they are not following a steamer, they may be seen employing the same method.

With a head-wind they advance with even greater ease. To understand how this is possible, some investigation of the air-currents behind the ship's stern is necessary. If small pieces of paper are thrown overboard when a strong head-wind is blowing, they are seized by a tremendous down-draught, but, some few yards astern, they suddenly dart up again. In fact, as the vessel moves onward, the air rushes down to fill the vacuum, then rebounds off the surface of the sea, and forms an up-current. Placing himself in this up-current, the gull is lifted as if he were no heavier than a scrap of paper, then he glides downward and onward. But as the vessel moves on, the up-current advances, or, strictly speaking, the point at which the up-current is formed. At the end of his descent the gull finds himself in this, is again lifted, and the process is repeated.

When the wind was not a due head-wind, but struck the vessel at a slight angle, now and then a gull would be seen apparently hovering motionless over the stern, of course really gliding onward with the vessel. Though I cannot speak with confidence of the explanation of this, the most wonderful of the methods employed, I wish to put forward what seems the probable explanation. The wind striking against the side of the vessel is deflected upwards, and it is this up-current which buoys up the gull as he floats over the stern. Though it may appear that his progress is perfectly uniform, I think it will be found that in advancing he descends slightly, that he often loses ground for a time, and that while losing ground he ascends. Thus the method in this case is really the same as in that last described. Unfortunately, I was not able to prove the existence of this up-current about 20 feet above the stern of the vessel. But there is good evidence of it in the fact that the gull remains suspended there without a motion of his wings. Without an up-current this would be an impossibility. It is to be hoped that good observers will give their attention to these very interesting phenomena. F. W. HEADLEY.

Haileybury, February 8.

Two Unfelt Earthquakes.

ON February 7, commencing at about 8 a.m., G.M.T., an unusually large, but, at the same time, unfelt earthquake was recorded in the Isle of Wight. The preliminary tremors, which include three well-defined maxima, extended over twenty-six minutes. After these came two periods of heavy movement, each extending over fifteen or twenty minutes. The duration of the whole disturbance was about one and one-half hours. It was Japanese in character, and because it was recorded in Tochia by Dr. G. Grablovitz, and at the same time was so marked in amplitude and duration, it is not unlikely that it disturbed the entire surface of the globe.

On the 13th there was a comparatively small disturbance, with preliminary tremors of three or four minutes, at about 10 a.m. I should be pleased to learn whether these earthquakes were recorded by bifilar pendulums in Edinburgh or Birmingham, or at any of our magnetic observatories. JOHN MILNE.

Shide, Newport, I.W., February 18.

FOUNDATIONS OF CORAL ATOLLS.

THE most regrettable failure of the boring lately attempted in the coral atoll of Funafuti has left us as wise as we were as to the actual structure of these formations; but the surveys carried on by H.M.S. *Penguin*, both at Funafuti and in the regions round about, have afforded information which, I think, is of value in elucidating some of the problems to be solved, and which has certainly strengthened some of my own views on the subject.

Funafuti, it may be mentioned, was selected for investigation as being one of a great Pacific group of atolls, which must have a common great cause for the formation of their necessary foundations, and for their development; groups which had a great share in causing Mr. Darwin to conclude, from the lack of other explanation of banks in large numbers at a proper depth for the growth of an atoll, that subsidence on a large scale was the predominant agent in their production ("Coral Reefs," 2nd ed., pp. 118, 119; 3rd ed., pp. 120, 121.)

Firstly, the sounding carried on by the *Penguin* round Funafuti and between separate islands of the Ellice Group, show incontestably that each atoll is situated on a separate mound, rising from a more or less even bottom of great depth below the surface. This proves that there has never been anything of the nature of a range of continental land which has gradually sunk beneath the waves. Each atoll, if it has sunk, has subsided independently, with its own isolated volcanic peak.

Secondly, the *Penguin*, while searching the seas some 250 miles to the south-westward of the Ellice Islands for several reported dangers to navigation, explored four banks, all of submerged atoll form, lying near one another.

The remarkable thing about these banks is the absolute uniformity of the depth of water over their areas, inside the low rim of growing coral which encircles their edges in various degree. This depth is 24 to 26 fathoms. The banks are large: one is 22 miles by 10; another is 18 miles by 9; the third is 8 by 7; and the fourth 4 by 3. The plan of one of them is given on the next page as an example.

Another bank, investigated a few years ago by H.M.S. *Waterwitch*, and lying 400 miles to the eastward, presents similar characteristics, and the same depth over its central area. All these banks are situated in a region exposed to the same conditions of wind and sea.

What causes this remarkable similarity of depth and this extraordinarily even surface over these large banks? Is

it uniform subsidence of mounds, of identical height, over a great area? Is it building up of mounds to an identical distance below the surface? I cannot think that either can account for the conditions. I would venture to suggest the cutting down of volcanic islands by the action of the sea, and that this operation has a far greater share in furnishing coral foundations than has generally been admitted.

The operation has not been overlooked. Mr. J. Murray says: "Volcanic mountains . . . like Graham Island, might be wholly swept away, and only a bank with a few fathoms of water over it be left on the spot. In this way numerous foundations may have been prepared for . . . even atolls" (*Proc. Roy. Soc. Edin.*, vol. x. p. 507). Sir A. Geikie, in referring to Murray's views, says, "those portions of volcanic mountains that rise above the sea-level are worn down by the atmosphere and waves, and unless otherwise preserved, must eventually be reduced to the lower limit of effective wave-action, which is probably nearly coincident with the lower limits of reef builders."

I can find, however, but little further reference to it, and prominence has not been given to it as a principal cause, as has been given to, on the one hand, subsidence, or, on the other, the building up of mounds by organisms other than corals.

Darwin specially rejects it. He says ("Coral Reefs," 2nd ed., p. 124): "It will probably occur to those who have read Ehrenberg's account of the reefs of the Red Sea, that many points in these great areas may have been elevated, but that, as soon as raised, the protuberant parts were cut off by the destroying action of the waves: a moment's reflection, however, on the basin-like form of the atolls, will show that this is impossible; for the upheaval and subsequent abrasion of an island would leave a flat disc, which might become coated with coral, but not a deeply concave surface; moreover, we should expect to see, at least in some parts, the rock of the foundation brought to the surface."

Let us now consider the general condition of the material piled up by a submarine volcano.

I find that David Forbes (*Geol. Mag.*, 1870, p. 323) is of opinion that erupted lava meeting water will assume the form of scoriæ, tufa, ash, and similar loose and subdivided matter, and I believe that many other geologists will agree. Instances of recently-formed volcanic islands add testimony to the correctness of this view. Graham Island, near Sicily, was all ash, and quickly disappeared. The new island in the basin of Santorin, formed in 1866, is all ash, as I know from personal investigation. Falcon Island, near the Tonga Group, which appeared in 1885, is all ash, and is now reduced to a small proportion of its original dimensions. Sabrina Island, on the flank of St. Miguel in the Azores, was formed in 1811, all of loose material, and was washed away to a depth of 15 fathoms in a short time. What water is now over it is not known.

No doubt when an ash mound has assumed sufficient dimensions to resist the percolation of water, the lava will be poured out in a mass and solidify, and form a mountainous island of the familiar oceanic type; but it appears to me that all the evidence goes to show that an enormous proportion of the material ejected by a submarine volcano will be loose, until a great height above the sea is attained.

If this be granted, here is an easy material for the sea to work upon. The next point is, to what depth does the action of the sea attain?

To those unacquainted with the ocean it may seem incredible that it can be in motion sufficiently violent to, at depths of 50 and 60 fathoms, move material; but I think that there is good evidence of it.

An isolated rock exposed to the full strength of the sea from one of the great oceans will cause a heavy breaker on the surface, when it is submerged as much as 10 fathoms. Let us think for a moment what this means, and what the horizontal velocity of the water at the depth of the rock must be to cause such a disturbance at the surface.

All who have studied the submarine contours of the land exposed to the great oceans, will know the remarkable fact that there is in the great majority of cases a sudden steeper fall at the depth of from 80 to 100 fathoms. This can only be explained on the supposition that the material eroded from the coasts can be moved and distributed to that depth.

The depth at which matter can be moved will, of course, vary with its size and tenacity. It is sufficient for my purpose if it is only fine mud and sand which is acted upon at such a depth as 80 fathoms, although submarine cables have been taken up which show evidence of having been moved and chafed at even greater depths.

Cables have been recovered which show that breakage has occurred from their being moved in 260 fathoms, and, by the kindness of Mr. F. Lucas, I have in my own possession a steel wire forming part of the outer covering of the Brazilian cable, picked up from 140 fathoms, which is worn down on one side as with a file. The records of the Cable Companies can furnish numerous similar instances.

While there are, as might be expected, banks in the oceans of every conceivable depth, there are a very large number with a depth over them, which is to my mind conformable to the depth to which wave action extends.

I may instance the great bank on which the Seychelles Islands stand. This is roughly 16,000 square miles in area, and has a general depth over it of 30 fathoms, though it is not so absolutely flat as banks less gigantic.

In the course of recent hydrographical operations it has been gradually borne in upon my mind that banks at great depth can reveal themselves upon the surface. Numerous instances have occurred where, on search being made for the cause of reported "breakers," deep banks, some lying as far below the surface as 800 fathoms, have been found on the spot, but nothing shoaler could be detected. "Rips" have, however, been seen in the course of the search, and steered for in the expectation that shallow water existed, but to no purpose. In such cases it seems probable that it is the tide (which extends to the bottom of the sea) meeting the obstacle of the bank, which is accelerated to such an extent that it affects the surface.

I have, therefore, no difficulty in believing that volcanic ash can be moved at depths of 30 fathoms, or more, when exposed to the action of waves in an otherwise deep sea, over which strong winds are continually blowing.

The effect will be to cut down an island more or less rapidly, according to its constitution, to a very considerable depth below the surface; the final result being a perfectly flat bank.

Mr. Darwin, as above quoted, speaks of a flat bank as unrepresentative of the floor of an atoll; but I think that this was a consequence of the comparatively small amount of facts at his disposal.

I have no hesitation in saying that a flat floor is an invariable characteristic of a large atoll, and I cannot find his "deeply concave surface" in any large atoll. On the contrary, a flat surface is found in all of these, whether the rim be above or below the surface.

It is true that towards the sides of a lagoon the depth gradually lessens; the encircling rim is not so steep as it is on the outside, but I think this is only what would be expected from the less vigorous growth of coral on the inner side of the rim as it rises, and from the gradual dissemination of débris from the rim thrown over by the waves.

I fail to see how subsidence of a solid peak, or the elevation of a submerged peak by the growth of

organisms, will explain a flat floor, without bringing in the action of the sea at considerable depths. In a subsiding peak with a barrier reef, there cannot be sufficient wave-action to level a large lagoon. In a bank rising by growth, why should it become level over its whole surface?

A further point remains. Can coral settling on a bank, 30 fathoms or so beneath the surface, form an atoll? Mr. Darwin limits this possibility to "some fathoms submerged," and considers that "it is an assumption without any evidence that at a depth at which the waves do not break, the coral grows more vigorously on the edges of a bank than on its central part."

I think that the experience of the years since Mr. Darwin wrote that, has given us evidence that this is not an unwarrantable assumption.

The instances of shallow narrow rims, or of isolated patches of coral on the edges of such banks, are now innumerable.

It is so well recognised that the edge of such a bank is the place to expect shoal patches, that in carrying out hydrographic surveys in coral regions it is the edge that is most minutely searched. On such edges are found evidence of coral colonies in every stage; complete ridges, broken ridges, and mere patches here and there.

Always, where means have permitted, is evidence brought up that such colonies are alive. There may be dead rims, but they are the exception.

The fact of a current, whether tidal, or otherwise induced, being accelerated on meeting a submarine bank is, I think, sufficient to account for this. The water pours over the edge of the bank, and brings abundance of food to those corals which settle on it, to the disadvantage of those settling further in.

The phenomena of coral patches and ridges on the edge of these submerged banks is so frequent, that I know not how they can be otherwise explained. The great Seychelles Bank is lined all round its edge, so far as examined, with such coral ridges and patches. The small islands, in this case of primary rock, in the centre of this bank are lined with fringing reefs; and if the whole bank, 150 miles in length, has uniformly sunk, they must have sunk too, and the fringing reefs would be beneath the surface.

Given these edgings of vigorous living coral on submerged banks, of which I consider we have indisputable proof, they will certainly grow to the surface and form the complete atoll. In the earlier stages calcareous organisms of all kinds will settle all over the bank, giving it a coating more or less thick according to circumstances.

The only other point that need be mentioned is the steep slope that characterises some atolls. As to this, I believe that masses with irregular projections like broken coral, falling down in water, will entangle themselves, and lie at a steepness of slope unknown in similar falls on mountain sides, and though the aid of subsidence may be needed for the almost vertical walls which occasionally occur, that the slopes of most atolls can be explained without it.

There seems no necessity to call in the aid of Murray's theory of deepening and widening of the lagoon by solution, but I am not contending that it may not so act. What I am concerned to show is that without it, and without subsidence, deep and large atolls may be formed, and that we have abundant evidence of atolls so forming.

I am not arguing that there has been no subsidence; indeed, I think that a volcanic cone, from the nature of its loose material, will frequently subside, and that some of the deeper lagoons may owe their depths of 50 fathoms or so to such a movement, quite apart from subsidence of large areas which we know occurs. Nor do I say that volcanic mounds that have failed to reach the surface, may not be built up to a sufficient height for corals to flourish; nor that all foundations and atolls have been formed in the same way; but I put forward the hypothesis that the cutting down of volcanic islands by wave-action and currents, has had a greater share in providing suitable bases for coral atolls than any other process of nature.

I may further suggest, in defence of my views, that it tends to explain why, over vast groups of atolls, no central summit is left. W. J. L. WHARTON.

FRIDTJOF NANSEN'S "FARTHEST NORTH."[1]

WHEN Gerrit de Veer published his "True and perfect description" of Barents' voyages for the discovery of a North-east passage, "so strange and woonderfull that the like hath never been heard of before," he justified himself for doing so by several reasons:—

"And also to stoppe their mouthes, that report and say, that our proceeding therein was wholly unprofitable and fruitelesse; which peradventure in time to come, may turn unto our great profite and commoditie. For he which proceedeth and continueth in a thing that seemeth to be impossible, is not to be discommended; but hee, that in regarde that the thing seemeth to be impossible, doth not proceed therein, but by his faint-heartedness and sloath, wholly leaveth it off."

This might not inappropriately be taken as an apology for Nansen's popular account of his great Arctic journey, which in many ways finds its nearest prototype in the classic adventures of the Dutch explorers three hundred years ago, when the lifting of a ship on the ice without being nipped was first observed, and the nature and effects of ice-pressures were first clearly described. For an example of a Norse Arctic explorer visiting England and receiving a Royal welcome, we must go back a thousand years to the time when King Alfred entertained Othar, and gave in a gloss on his Orosius the first record of Arctic discovery ever written in the language of the English. But between the visits of Othar and Nansen the progress of Arctic discovery has been due mainly to our countrymen, who have purchased with their lives much of the experience on which the safe and successful voyage of the *Fram* was planned.

These large and handsome volumes, giving the full narrative of the voyage, have been very rapidly prepared, too rapidly for the careful reader, who has been sacrificed to allow the eager public to revel in a story of adventure. More leisurely preparation might have left the book no less readable, and made it much more valuable, by including at least a few preliminary reports on the results of the voyage which must necessarily be of "great profite and commoditie" in many branches of knowledge. The revision of the text might have been more complete, the cumbrous title-page might have assumed a pleasing form, there might have been a prefatory note acknowledging the author's debt to the translators, whose work certainly deserves recognition, and the maps might have been of a less provisional character. Scientific readers will, however, be content to await the full discussions by specialists, which are doubtless in preparation, and meantime they cannot dip into the narrative of the most successful of all Arctic voyages without becoming absorbed by its peculiar fascination. The glamour of the Arctic regions has been felt by almost every explorer, and not a few have succeeded in passing it on to the readers of their books, but none so perfectly as Dr. Nansen. Too often the tale

[1] Fridtjof Nansen's "Farthest North," being the Record of a Voyage of Exploration of the Ship *Fram*, 1893-96, and of a Fifteen Months' Sleigh Journey by Dr. Nansen and Lieut. Johansen. With an appendix by Otto Sverdrup, Captain of the *Fram*; 120 full-page and numerous text illustrations, 16 coloured plates in facsimile from Dr. Nansen's own sketches, etched portrait, photogravures and maps. 2 vols. Pp. 1200. (Westminster: Archibald Constable and Co., 1897.)

of human suffering, and the tragedies of the retreat towards relief expeditions which have missed their mark, darken the records of Arctic travel. But here there is no tragedy. The necessary killing of the sledge-dogs to support the life of the rest is the harshest feature, and that seems to have seriously disturbed the equanimity of the kind-hearted explorers. To any but hardened sportsmen the pathetic display of maternal and filial affection between polar bears or walruses and their young, brings the cruelty of hunting man into painful relief; but happy, indeed, is that Arctic expedition in which sympathy for suffering is enlisted on behalf of the lower animals alone.

The pictorial power of Nansen's descriptions of the Arctic night, or the mysterious solitudes of the ice-fields, need not be dwelt on here, nor shall we linger on the psychological aspect of the expedition, the alternations of hope and doubt, the reminiscences of home as familiar anniversaries came round again and again, but proceed rather to point out some of the practical deductions to be made from the voyage. The preliminary scientific results having been already referred to in NATURE (vol. lv. p. 352), need not be repeated; but it is interesting to compare the actual experiences, detailed in the book,

[*Copyright by Archibald Constable and Co.*, 1897.

FIG. 1.—Cleaning the Accumulators before stowing away.

with the original project as described in the *Geographical Journal* (vol. i., 1893, p. 1) and summarised in NATURE (vol. xlvii. p. 65).

The ship answered the purpose for which she was designed exactly. The rudder was unshipped through the rudder-well, and kept on board during the greater part of the drift; but it was not found necessary to unship the propeller, which sustained no damage from the ice. Despite the great strength of the ship, and the wonderful freedom from strain, even during the severest ice-pressure, a good deal of water found its way on board during the summer months, but the leakage was found quite insignificant when the ship was floated after her three years on the ice. The lifting of the vessel by ice-pressure took place exactly as predicted, and she lay on the ice on a nearly even keel almost all the time, recovering her position spontaneously after being heeled over by heavy pressures. The non-conducting walls of the saloon entirely obviated the bugbear of all former expeditions—the condensation of moisture on the roof and sides, which, running down, saturates the cushions and bedding. With the fire lighted, the saloon was perfectly dry, and so warm that the fire was usually dispensed with. The arrangement for the supply of light was not quite so satisfactory. The engine was taken to pieces when the *Fram* was fairly beset, and the dynamos were worked for the first two years by a windmill, which gave good results. Early in the third winter the windmill wore out, and Sverdrup took it down; the accumulators were cleaned (see Fig. 1) and packed away. The men on board had so much necessary work to do with observations, shifting the boats and emergency stores, which were always kept on the ice, and had to be closely watched on account of the appearance of cracks, that there was no time to work the dynamo by means of a capstan and multiplying gear, as originally planned, and so for the longest and darkest winter of all there was no electric light.

The health throughout seems to have been perfect. The weight of all the members of the expedition increased. We read of Nansen suffering from lumbago for a day or two, of Sverdrup being laid up once with intestinal catarrh attributed to a chill, of a few slight frost-bites, a little snow-blindness, but nothing worse. There was no threatening of scurvy, and the doctor had no professional work to do beyond weighing himself and his companions, and counting the red blood-corpuscles once a month. All the food taken proved perfectly satisfactory, except some pemmican prepared with cocoa-nut fat, which even the dogs declined after once trying it. In every particular the equipment and provisions of the expedition were in excess of the actual requirements, and nothing not taken, except a long sounding-line, seems to have been wanted. Dr. Nansen attributes the good spirits and harmony of the expedition largely to the fact that all thirteen members lived together, eating the same food at the same table, and sharing the same work; he was much gratified with the complete success of this novel social experiment.

The *Fram* left Vardö on July 21, 1893, embarked a number of Siberian sledge-dogs at Khabarova, and entering the Kara Sea on August 4, coasted along the north of Asia, discovering many new island groups, and encountering no serious difficulty until September 25, when in latitude 79°, north of the Lena Delta, she was frozen into the ice-floe and commenced her drift. The first two months were spent drifting in various directions, but mainly south-east. Then a change occurred, and a north-westerly drift set in very slowly and irregularly, with many diversions to southward, while the ice under the *Fram* steadily increased in thickness.

On February 2, 1894, the crossing of 80° N. was celebrated; on May 15 81°, on October 31 82°, and on December 25 83° were successively attained. On January 6, 1895, the *Fram* was further north (83° 34′) than any previous expedition had reached, and it was a year and a half before she returned again to recorded latitudes. March 3 brought her to 84°, due north of Cape Chelyuskin, and on September 22 she crossed 85°, going north-west. For four months she remained north of 85°, and the sun remained invisible below the horizon for five and a half months—from October 8, 1895, to March 24, 1896. This was the longest and darkest winter ever experienced by man; but Sverdrup, in his record of it, makes light of its tedium, and notices no decline in the general health of himself and his ten comrades. On November 15, 1895, the northward component of the westerly drift ceased to act in latitude 85° 55′, longitude 66° 31′ E., and from that date there was a southerly component, increasing until the drift was due south in April. On May 19, 1896, steam was got up for the first time, and the fight to escape from the ice-floe commenced. Sverdrup blasted the vessel free, and worked her slowly through the lanes, as they appeared in the breaking pack, for 180 miles, at length reaching the open sea and sighting

the north-west point of Spitzbergen on August 13, 1896, after having been for 1041 days out of sight of land.

While the *Fram* was tracing out her intended path in comparative tranquillity the originator of the expedition, with one companion, was engaged on a far more adventurous journey. Nansen and Johansen left the comfort and plenty of their safe quarters on board on March 14, 1895, and pushed northward over the hummocky ice with dog-sledges carrying kayaks, until April 4, when the failure of the dogs made it necessary to turn in 86° 14′ N., nearly 200 miles beyond any former seeker of the pole. No land was seen, only an interminable floe. By May 19 they were back at 83° 20′, and but for the misfortune of allowing their watches to run down, and so losing their longitude, they would in all probability have reached Spitzbergen in the autumn of 1895. It was the one error of the expedition, and it was heavily paid for, for it involved the dismal wintering in a miserable hut on "Frederick Jackson's Island," living on bear and walrus meat from August 26, 1895, to May 19, 1896. A month's journey southwards in the spring brought them to Mr. Jackson's headquarters at Cape Flora, whence they sailed in the *Windward* on August 7, and returned safely to Vardö on the 13th.

The more one thinks over the details of this expedition the more remarkable does it appear. The strong current which Nansen believed to cross the polar area was not indeed found quite as he expected it, but there was an average drift due to prevailing winds in the predicted direction and of the predicted velocity. No land whatever was encountered, but a sea nearly two thousand fathoms deep. The resourcefulness of the leader is shown in his making a long sounding-line from one of his wire cables which was untwisted for the purpose in a ropewalk extemporised on the ice. The deep sea was fortunate, for the danger of a vessel being nipped and crushed is always greatest when the floating ice is driven against a resisting shore. Possibly the *Fram* would have resisted any pressure, for even in the severest trial to which she was subjected, when the advancing pressure-mound rose high on the rigging and the noise of the crashing ice was louder than thunder, she did not sustain the slightest damage. The photograph reproduced in Fig. 2 shows the crew of the *Fram* cutting away the pressure-mound of ice that had been hurled against one side of the vessel.

Little as either Nansen or Sverdrup makes of the dangers, and cheerily as their comrades bore themselves throughout, no one reading this book can fail to feel the profoundest respect and admiration for every one of them; and the public of this country has testified this to Nansen by a reception such as no scientific man or traveller has received before. This is a tribute to the calm and unswerving pursuit of an idea based on sound reasoning, and carried into effect by the highest personal qualities of courage, faithfulness and brotherly kindness.

[*Copyright by Archibald Constable and Co.*, 1897

FIG. 2.—Digging out the *Fram*, March 1895.

Many points invite special notice, such as the interesting descriptions of the formation of pressure-mounds (hummocks) and cracks in the ice, even during the coldest weather. The occasional spells of high temperature in winter are suggestive of föhn effects; but these will, of course, be duly discussed in the scientific report. One very extraordinary phenomenon, known as "dead water," was noticed in the Kara Sea, and we hope that such observations were made at the time as will enable its true nature to be discovered. It is described (vol. i. p. 174) as a layer of fresh water which is carried along by the ship, slipping over the surface of the salt water below, and retarding the progress of the vessel. How a steamer with the propeller working in strong sea water can fail to cut through a superficial layer of fresh water, is very difficult to understand.

HUGH ROBERT MILL.

THE DISCOVERY OF ANOTHER CONNECTING LINK BETWEEN FLOWERING AND FLOWERLESS PLANTS.

NEWS has recently reached Europe, from Japan, of a botanical discovery of unusual interest and importance. Two investigators, Prof. Ikeno (*Botan. Centrabl.*, 1897, 1) and Dr. Hirase (*ibid.*, 2 and 3), working independently, have observed the formation of antherozoids—bodies which have hitherto been regarded as exclusively confined to flowerless plants—in two groups of gymnosperms.

It is well known that in a large number of cryptogams, including all the higher forms, the process of fertilisation is intimately connected with the presence of water. The spores (or, at any rate, certain of them) give rise on germinating, sooner or later to cells from which free-swimming antherozoids are liberated. Each of the latter consists of a loosely coiled nucleus ensheathed in protoplasm, which is especially abundant at the anterior end of the body, and from it arise the cilia which enable the antherozoid to move through water.

In the flowering plants, on the other hand, with their special adaptations to a terrestrial mode of existence, it is of obvious disadvantage to depend on the precarious presence of water as the means of enabling the male sexual cell to find the female, and we find that the motile antherozoids are replaced by quiescent male cells, which are conducted to the female organs along a tube—the pollen-tube—which is a direct outgrowth of the spore or pollen-grain.

Now the gymnosperms, whilst they share with the rest of the flowering plants many characters in common, including the possession of a pollen-tube, yet differ from them in other important respects and approximate more nearly to the higher cryptogams. It is to the brilliant work of Hofmeister, more than forty years ago, that the recognition of this fact is primarily due, and it is, perhaps, a matter for surprise that a group occupying such an admittedly important position should not have been long ago subjected to a more searching scrutiny than it has received. It is true that Strasburger has added much to our knowledge; but, perhaps, the first really illuminating discovery since Hofmeister's time was that made by Belajeff in 1891, which was confirmed and extended by Strasburger in the following year. It was there shown that, whereas the similarity between the female prothallium and its products with the corresponding structures in cryptogams had already been recognised, a closer investigation into the process of germination of the pollen-grain also yielded quite unlooked-for resemblances to the homologous stages in the lower plants, clearly confirming the near kinship of the two groups.

But the presence of a pollen-tube, which would seem to render the formation of antherozoids superfluous, if not indeed directly disadvantageous, still appeared as one of the sharply-drawn distinctions between the zoidogamous cryptogam and the siphonogamous phanerogam. It is in the successful bridging over of this gulf that the great importance of the new discovery lies.

The two gymnosperms, *Cycas revoluta* and *Gingko biloba*, in which antherozoids have just been found, are both ancient types, and closely resemble each other in the mode of the formation of their male sexual cells. At first the pollen germinates much as in the other higher plants, forming a pollen-tube which penetrates the ovule, and containing a group of cells from one of which the antherozoids are ultimately derived. But unlike other forms which have been thoroughly investigated, the pollen-tube remains short, and although it may branch, it does not reach the archegonia in which the female cells are contained. The archegonia themselves lie round the base of a depression situated at the apex of the prothallium, and the space above them is stated to contain a watery fluid. The two generative cells, which have travelled to the end of the rudimentary pollen-tube, now become differentiated into antherozoids. The nucleus, which is large and egg-shaped, lies enclosed in protoplasm, and the latter alone supplies the material for the formation of the coiled anterior portion of the body. Cilia are formed on the coil in great numbers, and are able to impart a progressive, rotatory motion to the antherozoid. Dr. Hirase, who studied their behaviour in *Gingko* while alive, was able to watch them actually moving, and probably the same is true of Cycas, although, owing to the material having been killed, this, of course, could not be tested in the case of the latter plant. They are large bodies, measuring about $82\,\mu \times 49\,\mu$, and escape from the end of the pollen-tube, reaching the necks of the archegonia by swimming through the intervening water.

In reading the short account, as yet published, there is a point of especial interest which strikes one, namely, that the plant must have already begun to eliminate the element of risk which a dependence on a mere chance supply of water entails, by itself secreting the liquid necessary to enable the antherozoid to accomplish its mission. As soon as this habit has been developed it becomes intelligible how, in these more primitive examples, the spore might proceed to swell and finally put out a protuberance on the side nearest the water-supply. And the more effectively this was carried through, the less would be the chance of missing fertilisation. Thus it becomes comparatively easy to reconstruct, at any rate theoretically, the transitional stages between zoidogamy and siphonogamy. J. B. F.

HUMAN INCUBATORS.

IN a recent number of *L'Illustration* an account is given of an incubator used for rearing delicate children. The apparatus designed by Dr. Tarnier, Professor of the Faculté de Paris, was first used, in the year 1880, at the Paris Maternity Hospital: it is constructed on the same principles as the incubator used for hatching the eggs of poultry.

The apparatus, as first designed, consists of a large cubical box of thick wood, standing on a pedestal. This box is divided into two compartments, of which the lower contains a reservoir of hot water, and the upper the bed of the infant. A movable glass shutter forms the top of the apparatus, through which it is possible to observe the changes occurring inside, and take the readings of the thermometer placed near the infant. One side of the compartment is so hinged as to open like a door. The whole of the upper part is warmed by means of the hot water underneath, the warm air rising through holes at each end of the bed, and escaping through orifices situated at the top. The temperature of the water is so regulated that the temperature of the apparatus never exceeds 30° to 37° Centigrade. The weaker the infant is, the greater the temperature required.

Dr. Tarnier, with the help of his house surgeon, M. Auvard, lost no time in improving this apparatus. His latest design does not differ very much from the one described above; it has, however, the advantage of being more simple in character, and also lighter in construction. (Fig. 1.) The external dimensions measure $65 \times 30 \times 50$ centimetres, the thickness of sides being about 25 millimetres. The upper part of the case is divided into two sections, one being a wooden fixture, L, about 13 centimetres wide, and having a circular opening 4 centimetres in diameter at its middle part, to which may be attached a small helix, H. The rotation of this helix indicates the existence of a draught of air through the case. The other section is a glass shutter, V, which also serves as door.

The interior of the case is divided into a lower and

upper compartment by means of a shelf, D, extending almost across. The circulation of the air is as follows: air from the outside penetrates into the lower compartment through an opening, T, in the side; it acquires there a suitable temperature from the heaters, M,

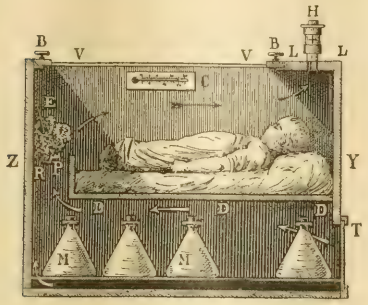

FIG. 1.—Dr. Tarnier's New Apparatus.

and rises into the upper compartment, moisture being obtained by its passage through a wet sponge, E. These heaters are capable of holding three-quarters of a pint of water. Five of these can be used at one time in the apparatus; but four are found sufficient to maintain the required temperature of 31° to 32°, provided the room is not less than 16°.

The infant is generally kept in the incubator from seven to fourteen days. This is about the *average* time, but it varies considerably, and cases have been known when the period has been extended to five weeks. The child may be taken from the incubator every two hours to be fed; but it must only be exposed to the air as short a time as possible, and care must be taken that the room is of a suitable temperature.

It is of interest to notice the decrease of mortality. The usual percentage of deaths of infants under 2000 grammes is 66 per cent., but by the use of the incubator this high figure is reduced to 36 per cent. Of those children born prematurely, few only survive; whereas it is now possible to save about 45 per cent.

While great care is taken to help to maintain the heat of the body of the child, it is also necessary to allow its system to renew that heat. If, therefore, the child is not strong enough to take food, some means must be taken of injecting it. In this case a probe, consisting of an india-rubber tube, with a graduated glass funnel at the end, is used. This instrument is inserted in the mouth, and pushed gently down the throat, and going a distance of fifteen centimetres, reaches the stomach. The probe is pressed, and sends the milk into the funnel until a sufficient quantity has been administered, when it is rapidly removed to prevent the return of the fluid.

Judging from the accounts which have been published, the improved apparatus seems to be very successful.

NOTES

THE following remarks, abridged from an editorial in the February number of the *American Naturalist*, will be cordially supported by many men of science on this side of the Atlantic:—"While the primary object of the university is instruction, there are several reasons why original research is of more than incidental importance to its prosperity. The mastery of his subject, which is characteristic of the man who advances the knowledge of it, is an essential of a good teacher. The belief in this truth is so general, that the teacher who is known as a discoverer will more successfully attract students to his classes than he who is not so known. But, apart from this, the general reputation of a school before the public is more surely affected by the research work that issues from its faculty, than the managing bodies of some of them seem willing to admit. We believe that those universities which permit of the production of original work by those of its professors who have proven themselves competent for it, are wise above those who do not do so. Those who load such men with teaching, so as to forbid such work, reduce their prosperity. The managers will be wise to preserve for these men sufficient leisure to enable them to advance the frontiers of the known, and thus to obtain juster views of things as they are, and to bring us ever nearer to a comprehension of the great laws, whose expressions it is their business to teach to the growing intelligences of the nation."

THE Société Industrielle du Nord de la France has awarded a gold medal to M. Moissan, in recognition of his scientific investigations.

THE Council of the Sanitary Institute have accepted an invitation from the City Council of Leeds, to hold a Sanitary Congress and Health Exhibition in that city in the month of September next.

ACTING under the provisions of a rule which empowers the annual election by the Committee of nine persons "of distinguished eminence in science, literature, the arts, or for public services," the Committee of the Athenæum Club have elected Dr. David Ferrier, F.R.S., Professor of Neuro-pathology at King's College, London, a member of the Club.

THE Council of the Society of Arts attended at Marlborough House on Tuesday, February 16, when his Royal Highness the Prince of Wales, K.G., President of the Society, presented the Albert Medal to Prof. David Edward Hughes, F.R.S., "in recognition of the services he has rendered to arts, manufactures, and commerce, by his numerous inventions in electricity and magnetism, especially the printing telegraph and the microphone."

THE new building for the South African Museum at Capetown has now been completed, and fitted with the so called "Dresden cases," which are made entirely of glass and iron, and are believed to be absolutely dust-proof and air-tight. Under the superintendence of Mr. W. L. Sclater, the Director, the collections are in process of removal from their former quarters into the new building, which is expected to be opened to the public by March 1.

WE regret to record the following deaths of men of science abroad:—Dr. Timothée Rothen, Director of the International Telegraph Bureau at Berne, and author of numerous treatises on telegraphy and telephony.—Prof. Karl Theodor Weierstrass, Professor of Mathematics in the University of Berlin, and Foreign Member of the Royal Society.—Prof. M. Klimm, Professor of Hydraulics in the Polytechnikum at Budapest.

REFERRING to Mr. Evans's letter in last week's NATURE, upon immunity from stings of bees, Mr. T. A. Gerald Strickland sends us a note on a similar case. A bee-keeper, having accidentally upset a hive, was so badly stung that he was laid up for a few weeks, but afterwards the stings of the bees did not affect him, though before his involuntary inoculation they caused great pain and swelling. The accident happened some years ago, but the bee-keeper was still indifferent to stings last autumn.

THE Royal Academy of Belgium has awarded gold medals, of value 600 francs, to Dr. C. De Bruyne, of Ghent, for his essay on the influence of phagocytes in the development of the Invertebrata; to M. G. Cesàro, of Trooz (Liège), for his essay on Belgian minerals; to MM. J. F. Heymans and O. Van der Stricht, of Ghent, for their conjoint paper on the peripheric nervous system of *Amphioxus*; and to M. Jean Massart, for his essay on the cicatrisation of plants.

The prosperous *Société de l' Industrie Minérale* of Saint-Etienne invites original communications from its members on mining, metallurgy and mechanics, for which the Council will award premiums varying from 500 to 1000 francs. The subjects to be dealt with are: in the mining section, the working of thick coal seams, and underground haulage by compressed air or electric locomotives; in the metallurgical section, the methods for removing dust from combustible gases, the manufacture of open-hearth steel, and the utilisation of the waste heat of furnaces for steam boilers; and, in the mechanical section, the use of high pressure, cut-off gears, compounding and condensation in winding engines, and the employment of superheating in steam engines. The papers must be written in, or translated into, French, and must be in the Secretary's hands by December 31, 1897.

THE international aerostatic ascents, which for some time past have been contemplated, took place on the 18th inst. at Paris, Berlin, and Strasburg. Three unmanned balloons were liberated at about 10 a.m. (local time) at each station. The German Emperor witnessed the Berlin operations, but the balloon burst. The Strasburg balloon disappeared in the north-east, and has not yet been recovered. The Paris balloon descended, after having travelled during a little more than two hours in the N.N. ¼ E., and ran 102 kilometres. The temperature recorded was 60°, at an altitude of more than 10,000 metres. An apparatus, constructed by Cailletet, for bringing back to land the air of the upper atmosphere, was successful, but the gas captured has not yet been analysed. The records are confused to some extent, but the balloons and instruments are safe.

MR. ALEXANDER WHYTE gives an interesting description of his travels in North Nyasa, in the *British Central Africa Gazette*, published at Zomba. Mr. Whyte stayed at Karonga for a short time, and then went through Napata to Chifungu's village, where he obtained some interesting specimens; among others, a fine oriole and a tiny little chestnut-backed owl, neither of which he had previously met; also a pretty little squirrel, only one of which he had previously collected. The botany of the neighbouring hills and valleys he found most interesting. Journeying from Chifungu's village, the hills became higher and only sparsely clad with stunted forest, short grass, and weird-looking deformed shrubs. One looked like a miniature four-foot baobab, afflicted with elephantiasis, the soft smooth-barked branches being abnormally thick and suddenly tapering to a sharp point. All the rocky ridges had a species of Velozia upon them. This species was similar in habit to the new one (*V. splendens*) discovered by Mr. Whyte on the Mlanje range, but the branches form a more acute angle with the stem, and it is believed to be another species. Near the Wyie River some interesting birds were collected; among others, a bright little kingfisher very similar to *Cayx tridactylus* of India and Ceylon. Following the Wyie River the grand Nyika range was eventually approached, and, after a stiff climb, the plateau of the range was reached. Towards the end of last November, Mr. Whyte was collecting zoological and botanical specimens on the top of Mlosa mountain and plateau. He reports that he has procured some interesting specimens, several of which he thinks are new to science. The top of Mlosa plateau consists of rolling hills covered with fine short grass, well-wooded in the gullies, and with a plentiful supply of water. The plateau is not quite equal in extent to the Zomba plateau, but lies at about the same elevation (between five and six thousand feet above the sea), and the scenery is even finer than that of Zomba. Access is obtained to the Mlosa plateau by more easy gradients than the Zomba plateau or that of Mlanje.

THE Gold Coast, Ashanti, and Kumassi, is the subject of an illustrated article, by Mr. George K. French, in the *National Geographic Magazine* for January. Mr. French journeyed from Cape Coast Castle to Kumassi, through Prahsu, or the Prah River, and the Adansai country, and his descriptions of the natives, as well as his photographs, are very instructive. It is satisfactory to see the expression of an opinion that "England's enlightened policy in other parts of Africa will undoubtedly be applied here, and will result in the ultimate spread of civilisation throughout this darkest part of the dark continent."

THE fourth number of the current volume of the *Mittheilungen von Forschungsreisenden und Gelehrten aus den deutschen Schutzgebieten* contains a number of notes of geographical and meteorological importance. An abstract is given of the results of several hundred boiling-point determinations made by Dr. Stuhlman and First-Lieut. Schlobach in Usaramo, Ukami, and Uluguru, during 1894-5: reduced with more intelligent care than is usually bestowed on such data. Lieut. Merker contributes a note, with sketch map, of two new lakes between Kilimandjaro and Meru. Further abstracts of meteorological observations at three stations in Konde—Manow, Wangemannshöhe, and Ikombe—are given, and also at Jaluit, in the Marshall Archipelago.

THE *Board of Trade Journal* makes the following announcements:—An Exhibition will be held at Bergen in Norway in 1898, to consist of an International Fisheries Section and of national sections for industries, agriculture, and fine arts. The grounds of the Nygård Park (Nygårdsparken) have been selected as the site of the Exhibition.—A Transmississippi and International Exhibition will be held at the City of Omaha, in the State of Nebraska, in the year 1898, for the exhibition of the resources of the United States of America, and the progress and civilisation of the Western Hemisphere, and for a display of the arts, industries, manufactures, and products of the soil, mine, and sea.—The Parliament of New South Wales has decided to hold an International Exhibition at Sydney in 1899. According to statements made in the House, the cost of the Exhibition will be 250,000*l.*, and the Australian products shown thereat will be sent to Paris in 1900.

THE connection between relative humidity and the manufacture of cotton fabrics, is probably too slender to be seen by the "practical man" in Great Britain, or to need any consideration from a practical British Government. In the United States, however, there are Government departments which frequently make inquiries into the bearings of natural phenomena upon industry. A few days ago we received a "Report on the Relative Humidity of Southern New England and other Localities," prepared under the direction of Mr. Willis L. Moore, Chief of the U.S. Weather Bureau, by Mr. Alfred J. Henry. Upon the face of it, one would hardly expect more than meteorological statistics and conclusions from this *Bulletin*. But mark how the facts work out. One of the conditions essential to the greatest degree of success in the spinning and weaving of cotton fabrics is a humid state of the atmosphere, and the more constant the degree of humidity the greater is the measure of profitable spinning, especially as regards the finer numbers. The average

spinning of England is finer than that of the United States, and the average of the latter varies greatly with geographical location, the finer spinning being done almost wholly in New England. The attention of the Weather Bureau having been called to the importance of the subject and to the probable extension of the manufacture of cotton over a much wider area than it has yet occupied, a comparison was instituted with a view of ascertaining how the natural humidity of certain portions of the United States, particularly the South, where the extension of the art is most pronounced, compares with that of the southern shore of New England. It is with the results of the investigation made in this connection that the *Bulletin* deals, and we have no doubt that the observations and conclusions from them will be used to advance cotton manufacture in the United States. The idea that the tendency to concentrate the cotton manufacturing industry in Lancashire was originally due to the advantage of climatic conditions, is, of course, not entertained. Indeed, it appears from the report that thus far in the development of the cotton manufacturing industry too little account has been taken of climatic conditions as affecting the quantity or quality of the output. For the benefit of enterprising cotton manufacturers the suggestion is made that the control of both temperature and humidity by artificial means seems to be the final solution of the problem in all cases where the establishment of mills in a relatively dry district is contemplated.

WE are pleased to notice a marked improvement in the first number of the new volume of the *Rivista Scientifico Industriale*, published in Florence. The editor and founder, Dr. Guido Vimercati, has now the co-operation of Dr. Carlo del Lungo. The most noteworthy feature of the present number is a complete bibliography of all Italian works relating to Röntgen rays published in 1896. It is the intention of the editors to deal with other branches of physics in the same manner in subsequent issues. The number is accompanied by excellent stereoscopic figures of an optical bench for interference experiments, illustrating a paper by Prof. G. Grattarola.

DR. G. TOLOMEI, writing in the same journal, describes an interesting series of experiments on the presence of argon in plants. The author inferred the absence of argon in fully-developed vegetable tissues. Experiments were also made with the nodule-forming Leguminosæ, and with their nitrifying bacteria, and the results were the opposite of that just cited. In the case of nitrogen obtained from the growing roots of a young pea, argon was obtained from the tissues, but in smaller quantities than from the culture of bacteria; and hence the author maintains that the argon fixed by the bacteria does not enter into chemical combination, on the ground that if it did so, it would, if once absorbed, remain in the plant instead of disappearing in the older tissues.

PROF. W. SOMERVILLE has carried out a series of comparative experiments to test the value of the pure cultures of the various varieties of bacteria that inhabit the roots of our more important Papilionaceous plants, now sold under the name of "nitragen." The investigation was described before the Botanical Society of Edinburgh on January 14. Experiments were made with peas, broad beans, lucerne, and broad red clover. Only in the case of the peas did the application of nitragen result in an increase in the yield, and even then the variations in the weights of produce were too small to make it possible to say definitely that the inoculating substance affected growth either one way or another. The experiments were carried out in a garden attached to the Durham College of Science, in which it may be assumed that peas and beans have frequently been cultivated during recent years. As the soil was thus well supplied with the bacteria that associate with the roots of these plants, Prof. Somerville agrees that it is not surprising that the application of a pure culture of these bacteria should have been inoperative. But as regards red clover and lucerne, neither of these plants has ever been cultivated in the garden, and the probability is that not a single plant of lucerne ever grew in the garden, or, indeed, in any fields in the neighbourhood. The conditions, therefore, were to be regarded as distinctly favourable for exhibiting the action of the specific bacteria of these plants, and yet they failed to produce any effect. Apparently some improvements are required in the methods of manufacture or application in order to make nitragen of service in agriculture and horticulture.

THE influence of intellectual work on the blood-pressure in man is the subject of a paper, by MM. A. Binet and N. Vaschide, in the January number of the *Psychological Review*. The instrument used by the authors was Mosso's Sphygmomanometer, which has the advantage of indicating the results by tracings. The method of experimentation consisted in taking the pulse under increasing pressure from 0 to 140 mm. of mercury: this test was made at first while the subject was in a state of rest, without excitement or preoccupation of any kind; then the same experiment was repeated while the subject was absorbed in a difficult mental calculation. Two tracings were thus obtained for comparison, and the differences between them could be attributed to the intellectual labour, unless some chance circumstance—as an emotion, a shiver, &c.—prevented the two experiments from being strictly comparable. From the results obtained, it appears that the maximum amplitude of the pulsation tracings was greater during rest than during intellectual work; it was 5 mm. in the former case, and only 3·5 mm. in the latter. During all the mental calculations, there was evidently a diminution of the pulse, as the result of a more or less marked vascular constriction. In both states, the maximum amplitude of the pulse appears to have been reached when the blood-pressure was 80 mm. Beyond this pressure, the amplitude decreased more rapidly during the state of rest than during mental activity, and a pressure of from 100 to 120 mm. was found to completely suppress the pulsation both in a state of repose and in a state of intellectual labour. To determine the difference between the circulation in a state of intellectual labour and that of rest, a counter-pressure of 110 mm. was chosen. A register of the pulse with this pressure was made for about half a minute, and then the subject was told to commence a mental calculation. The first three or four pulsations after he was told to begin were of the same character as the preceding ones, but afterwards the pulsations became twice and, often, three times as great. This increase in amplitude maintained itself, in general, without increase or diminution, and with great regularity during the whole of the mental calculation. When the problem had been solved, the pulsation gradually diminished, and finally reached the original condition.

THE fourth part of vol. ii. of "Fresenius' Quantitative Analysis," translated by Mr. Chas. E. Groves, F.R.S., has just been published by Messrs. J. and A. Churchill.

THE following are the arrangements for science lectures at the Royal Victoria Hall, Waterloo Road, during March:—March 2, "A Lump of Salt," by Prof. Holland Crompton; March 9, "Cyprus," by Mr. A. H. Smith; March 16, "The Valley of Kashmir," by Mr. Walter R. Lawrence; March 23, "Marine Food Fishes," by Mr. Gilbert C. Bourne; March 30, "Quicksilver," by Dr. H. Forster Morley.

THE *Boletin del Instituto Geológico de México*, by Dr. C. Sapper, describes the geology and physical geography of Yucatan. It includes chapters on the mineral and agricultural productions of the peninsula, and meteorological tables.

THE fifth volume of the *Journal of Malacology*, founded by Mr. Walter E. Collinge, and now edited by Mr. Wilfred Mark Webb, has been received. A valuable feature of each number is a descriptive bibliography of current malacological literature, compiled by Mr. E. R. Sykes and Mr. S. Pace.

THE *Bulletin de l'Herbier Boissier*, edited by Prof. Chodat, of Geneva, publishes a very interesting account, by the Belgian botanist Crépin and MM. Autran and Durand, of the plants cultivated by Boissier in 1885, the year of his death, in the gardens at Valleyres and Chambésy. The number of species enumerated is nearly 5000.

WE have received an important excerpt from the sixteenth annual report of the U.S. Geological Survey (1894-95). The subject is "Some Analogies in the Lower Cretaceous of Europe and America," and the author, Mr. Lester Ward. Mr. Ward devoted four years to a somewhat careful study of the Lower Cretaceous of America, especially of the Potomac formation; and he also spent a year or so in examining the structure of Portland, the Isle of Wight, and other typical localities. His own observations, and the work done by others, lead him to claim that certain general resemblances do exist between the Lower Cretaceous strata of America and those of Europe.

L. LORENZ'S "Œuvres Scientifiques," with notes by H. Valentiner, are being published at the expense of the Carlsberg Foundation. The first part of the first volume has just been issued by the firm of Lehmann and Stage, Copenhagen. It contains papers on the determination of the direction of vibrations of ether by polarisation of diffracted light, and also by reflection and refraction; on the reflection of light at the separating surface of two transparent isotropic substances; on the theory of light (two memoirs); and on the identity of the vibrations of light and electricity. The editor's notes on the papers are very full.

IN the years 1889, 1892, and 1896, Prof. Carl Rabl contributed three important memoirs on the "Theorie des Mesoderms" to the *Morphologisches Jahrbuch*. These papers have now been brought together and published in volume form, under the same title, by Wilhelm Engelmann, of Leipzig. The volume deals with the development and differentiation of the mesoderm, a subject to which Prof. Rabl has devoted much attention. To complete the work, a second volume, dealing with the differentiation of the mesoderm in the higher vertebrates, from amphibia upwards, will be published in the course of this year. We propose to review this important contribution to vertebrate morphology when it is completed, and content ourselves now with announcing the publication of the first volume.

THE scheme which the late Emperor of Russia set on foot for constructing a canal through Russia from the Baltic to the Black Sea, and which has been in abeyance since his death, has lately been revived. M. Flourens, the French Minister for Foreign Affairs, who in his private capacity was commissioned by Alexander III. to investigate the practicability of constructing a water-way for the passage of men-of-war from one sea to the other, has recently been to St. Petersburg, and had a conference with the present Emperor, and has been directed to consult the Ministers of Finance and Communication as to its practicability. The proposed canal would be 994 miles long, and would have a depth of 29 feet. It would start from the Gulf of Riga, follow the course of the Duna, the Beresina, and the Dnieper to the Black Sea, thus placing the naval dockyards of Libau in the north and Nikolaief in the south in direct communication. The estimated cost is £20,000,000. There is at the present time a navigation for small vessels and timber rafts along this route, but the way is interrupted by a long series of cataracts on the Dnieper, and very expensive works would have to be carried out to overcome these and the other obstacle in the way.

THE following lectures will be given at the Imperial Institute during the month of March, on Monday evenings, at 8.30 p.m.:—March 1, "Ceylon in Ancient and Modern Times," by Mr. H. W. Cave; March 8, "Imperial Aid to Solar Research, with an account of recent Eclipse Expeditions," by Mr. J. Norman Lockyer, C.B., F.R.S.; March 15, "Some Indian Dye-stuffs," by Prof. J. J. Hummel; March 22, "The Timber Supply of the British Empire," by Dr. W. Schlich, Professor of Forestry at the Royal Indian Engineering College, Cooper's Hill. In addition to these lectures, which are open to Fellows and persons introduced by them, a popular lecture, to which the public will have free admission, will be given at 8 o'clock p.m. on March 2, on "Queensland of to-day: some Notes on its Progress and Resources," by Mr. C. S. Dicken, C.M.G., Acting Agent-General for Queensland.

INTEREST in science is encouraged by the scientific societies connected with many of our public schools. The twenty-seventh annual report of the Wellington College Natural Science Society shows that varied and instructive meetings were held during 1896. Phenological observations were made, meteorological observations continuously recorded, and collectors of insects, plants, shells and eggs, showed enthusiasm in collecting and in determining species. The late Sir John Pender left a bequest in his will to permanently establish the Pender Prize, annually given by the Society for an essay on a subject connected with any branch of science. Preference is given to essays containing original work of any kind. Prizes of this kind are far more likely to create investigators, and thus extend a knowledge of the true inwardness of nature, than are prizes based upon the results of examinations.

THE tenth annual report of the Liverpool Marine Biology Committee and their Biological Station at Port Erin, by Prof. W. A. Herdman, F.R.S., is an excellent record of results. The large green *Thalassema*, of which several specimens, all more or less mutilated, were trawled from the deep water to the south-west of Port Erin at Easter, seems to be an undescribed form. Prof. Sherrington and Dr. Noël Paton have independently investigated the green pigment spectroscopically. They report that it is a very remarkable and apparently unknown pigment, which is not allied to hæmoglobin or chlorophyll. It is not a respiratory pigment, and is apparently nearer to "bonellein," described by Dr. Sorby from the Gephyrean *Bonellia viridis*, than to any other known pigment; but differs markedly in some respects, and cannot be identical with it. This is only one of the many interesting items in Prof. Herdman's report on work accomplished under the auspices of his Committee.

PROF. S. P. LANGLEY'S report on the operations of the Smithsonian Institution for the year ending with June 1896, has just been distributed. As has been already announced, the Institution has now completed its first half-century of existence. To commemorate this event, arrangements have been made for the publication of a memorial volume, which will give an account of the Institution, its history, its achievements, and its present condition. The volume will be a royal octavo of about 750 pages. It has been prepared under the general editorship of the late Dr. Goode, and will be found as worthy of the Institution as was every other task entrusted to his hands. The division is into two parts: one on the history of the Institution, and the other containing appreciations of the work of the Institution in different departments of science, written by various

men of science in the United States. The Institution has renewed for three years the lease of the Smithsonian table at the Naples Zoological Station. The table has been constantly occupied since October 1, 1893, the date of the first appointment, with the exception of May 1894. During the intervals of his official duties, Prof. Langley has continued to experiment with the aërodrome, until he has reached a measure of success which, he announces, justifies him in making the statement that mechanical flight has now been attained. On May 6 last, a mechanism, built chiefly of steel and driven by a steam engine, made two flights, each of over half a mile (see NATURE, vol. liv. p. 80). Since then Prof. Langley says this result has been doubled. In the astrophysical observatory Prof. Langley has continued his researches upon the solar spectrum. The results of the year's work are summed up by the statement that an entirely new stage of accuracy has been reached by the elimination of sources of error, of long standing, in the spectrobolometric processes, and that as a result of this accuracy it is expected that the positions of between 200 and 300 lines in the infra-red spectrum will shortly be published.

By his further investigation of the reversible decomposition of hydriodic acid gas, published in the February number of the *Zeitschrift für physikalische Chemie*, Mr. Max Bodenstein removes all doubt as to the normal character of this change, thus adding another to the very small number of reactions between gases which are known to follow the laws of mass action. In a former investigation he had found that, at a given temperature, the fraction of the hydriodic acid decomposed when equilibrium was attained was not independent of the pressure of the gas. Since the decomposition takes place without change of volume, theory indicates that, at constant temperature, the equilibrium should be unaffected by a change of pressure. This discrepancy is removed by the experiments described in the present paper. Known quantities of hydrogen and iodine are heated in sealed glass bulbs at a constant temperature until equilibrium is attained, whereupon the quantities of hydrogen, iodine, and hydriodic acid present are determined. This leads to the, at first sight, somewhat surprising result that equivalent quantities of hydrogen and iodine have disappeared. In one experiment neither hydriodic acid nor iodine were found in the heated bulb, the whole of the iodine used having disappeared. The cause of this loss is found in the combination of hydriodic acid with the glass; part of the iodine is found as sodium iodide; the greater part, however, appears to form some compound insoluble in water. When the diminution in the concentration of the hydriodic acid gas, to which the combination of part of it with the glass gives rise, is taken into account, it is found, in accordance with theory, that the fraction of the hydriodic acid decomposed, at constant temperature, when equilibrium has been reached, is independent of the pressure.

In a second paper, on the decomposition of hydriodic acid gas by sunlight, it is found that on prolonged exposure the whole of the hydriodic acid is decomposed; the change is thus not reversible. The intensity of the light remaining constant, the quantity decomposed in unit time is simply proportional to the quantity of undecomposed hydriodic acid present, and is not affected by its pressure (within the limits 0·5 and 1 atmosphere approximately). These are the characteristics of a monomolecular reaction, and it therefore follows that each molecule of hydriodic acid is decomposed independently, each ray of light, of proper vibration frequency, simply breaking up the hydriodic acid molecules in its path.

The addition to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*, ♂) from West Africa, presented by Mr. John Laxson; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. W. H. Camm; a Grey Lemur (*Hapalemur griseus*) from Madagascar, presented by Mr. W. B. Dyer; a Greater Vasa Parrot (*Coracopsis vasa*) from Madagascar, presented by Surgeon Lieut.-Colonel F. H. Gelbresa; an Upland Goose (*Chloephaga magellanica*, ♂) from the Falkland Islands, deposited; five Azara's Opossums (*Didelphys azarae*), ten Burrowing Owls (*Speotyto cunicularia*) from South America, eight Guira Cuckoos (*Guira piririgua*) from Para, two Uvæan Parrakeets (*Nymphicus uvæensis*) from the Island of Uvea, Loyalty Group, a Smew (*Mergus albellus*, ♀) from Holland, purchased.

OUR ASTRONOMICAL COLUMN.

Periodical Comets.—The present year seems to be somewhat barren of appearances of periodical comets, while, on the other hand, the two following years will be distinguished by the returns of several well-known comets.

This year's visitors are limited to three altogether, namely, 1890 VII., D'Arrest's, and Swift's. The first named seems, from all accounts (*Observatory*, No. 249), to be most probably very feeble in intensity, since at its appearance in 1890 it was an excessively faint object. The comet was described by Dr. Spitaler at Vienna, and a computation showed that it had a period of 6·4 years, so that it should make its perihelion passage on March 11. Those who wish to search for this comet will find an ephemeris in *Astr. Nach.*, No. 3370.

D'Arrest's comet, discovered at Leipsic in June of the year 1851, has also a period of nearly the same length, namely, 6·5 years. This comet has not been observed at every period, having been seen only in the years 1857, 1870, 1877, 1890. It is probable that even this year it will be missed, in consequence of its unfavourable position. A daily search ephemeris (March to August) for this year will be found to be given by M. G. Leveau in the *Bulletin Astronomique* for last month (January).

Swift's comet will not be seen, owing to the fact that it will be lost in the sun's rays, as the earth will be in the opposite part of her orbit to that nearest the comet at perihelion passage.

A comet that may be picked up again this year is Brooks' 1886 IV., and observations of this comet are wanted, as the period is not yet accurately determined.

A list of the comets which are due to appear in the next two years is quite a formidable one, as given by Mr. W. F. Denning in the current number of the *Observatory*:—

1898.		Comet.	1899.		Comet.
April	...	Pons-Winnecke.	Jan.	...	Denning (1881 V.).
May	...	Encke.	Mar.	...	Tempel (1886 I.).
June	...	Swift (1889 VI.).	April	...	Barnard (1892 V.).
June	..	Wolf.	May	...	Tuttle (1858 I.).
Sept.	...	Tempel (1867 II.).	May	...	Holmes (1892 III.).
			July	...	Tempel (1873 II.).

Observations of Mars at Meudon.—M. Perrotin, whose observations of Mars are very well known, commenced at Meudon, in December of last year, a series of observations of that planet. The instrument he used had a diameter of 0·83 metres, and he has been able to make some very interesting observations, which have been communicated to the *Comptes rendus* for February 15. A careful survey of the planet has led him to state that the disc is apparently divided, as regards general aspect and colour, into four zones lying parallel to the equator. Two of these comprise the equatorial regions. Further, he has noticed that at equal distances from the centre of the disc the surface details do not appear with equal facility in the four zones. The canals are always most distinct towards the middle of the disc, and they are visible for a further distance along a meridian than along a parallel. M. Janssen remarks, with regard to the latter point, that the observations show that the atmosphere of Mars contains bodies capable of condensing, and thereby of increasing the transparency of the atmosphere, as the polar regions are approached, which is in accordance with observations of the water vapour in the atmosphere of the earth. We may mention that the above observations are of special interest, since M. Perrotin is observing with a different instrument from that with which he has made all his previous observations.

THE EMBRYOLOGY OF THE NAUTILUS.[1]

NAUTILUS macromphalus is the species of nautilus characteristic of the New Caledonian Archipelago, which comprises the islands of New Caledonia, the Isle of Pines, and the Loyalty Group. I took up my residence on the shores of Sandal Bay, Lifu, in August 1896. Having collected a number of nautilus, I placed them in captivity in a large native fish-trap, specially fitted up, fed them twice or three times a week with fish, land-crabs, Palinurus, and Scyllarus, and on December 5, 1896, commenced to obtain the fertilised ova.

It is not necessary at present to describe the details of manipulation, and I therefore proceed at once to give a brief account of the more obvious features of the eggs as illustrated by the accompanying figures. The eggs are laid singly and at night, in concealed situations, and are firmly attached by a sponge-like reticulate area of attachment placed towards their hinder inflated extremity, usually on one face of the egg-case, but sometimes quite posteriorly to a suitable surface. I supplied the latter to the nautilus by fixing pieces of old sacking to the walls of the fish-basket, leaving loose, overhanging folds, beneath which the eggs could be well concealed. The fibres of the sacking were deftly employed by the nautilus in cementing their eggs.

The ovum is enclosed within a double casing, an inner closed capsule, and an outer capsule more or less freely open in front. The material of which the capsules consist is of a bright milk-white colour, and of firm cartilaginoid consistency. The capsules do not collapse, but retain their shape when allowed to dry.

For convenience of description, the exposed surface of the egg may be spoken of as the dorsal or upper side, while the

FIG. 1.—Fertilised egg of *Nautilus macromphalus* in the natural attached position. The pectinate ridges and fenestrations, together with the slit in the wall of the outer capsule, are well seen. The arcuate thickening in the middle of the posterior half of the egg is due to the fusion of the outer with the inner capsule. In this ovum the anterior membranous prolongations of the outer capsule were unequal, the larger of them having the form of a thin flattened expansion.

attached side may be referred to as the lower or ventral side. The outer capsule is separate from the inner capsule below and for about two-thirds of the upper side, but is fused with it in the postero-dorsal region. Where the two capsules are fused together the covering of the ovum is much thickened.

The egg with outer covering complete is of remarkably large size, attaining a length of 45 mm., everything included, with a width of 16 mm., and a maximum height of 16·25 mm. The length and the width are fairly constant in normally shaped eggs, but the height varies somewhat, some eggs being a good deal flatter than others.

In Fig. 1 an egg is represented as seen in its usual natural attached position. The depressed or "anterior" end of the egg is, as a rule, directed vertically upwards. The outer capsule is continued in front into two thin, translucent, terminal processes. For nearly half the length of the egg on the upper side the two halves of the outer capsules are separated by a narrow slit from one another and join together behind the centre of the egg. The dorsal ridge or suture of the inner capsule can be seen through this slit in the outer capsule. On the lower side of the egg the two halves of the outer capsule are continuous across the middle line throughout the length of the egg, except at the extreme anterior end.

The surface of the egg in the posterior inflated region is smooth, with a few slight folds like the folds of drapery, giving it a graceful appearance. The anterior depressed region is characterised by the presence of a number of pectinate ridges and of fenestrations in the wall of the outer capsule (Figs. 1–3).

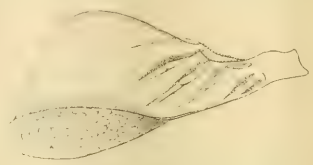

FIG. 2.—The same egg from the side, showing the inflated posterior or proximal portion and the more flattened distal portion, as also the spongy area of attachment.

Sometimes, however, the pectinations are obscure and the fenestrations may be absent.

Hardly will any two eggs present an exactly similar appearance. Sometimes there are shred-like processes from the surface of the outer capsule, lending a more or less tattered appearance to the egg.

In Fig. 4 another egg is shown with the above-described slit in the upper wall of the outer capsule, widened out so as to disclose the inner capsule to view.

The inner capsule has a regular oval shape with anterior pointed extremity and a generally smooth surface. Its wall has a finely striated structure, the striæ having a watery appearance. There are three distinct seams or sutures, representing lines of least resistance, in the wall of the inner capsule, namely, a median suture on the upper side (*i.e.* the side directed away from the attached side of the egg), and two lateral sutures placed towards the lower surface of the capsule (Figs. 4–6).

The dorsal suture is marked by a prominent ridge which is produced in front beyond the anterior extremity of the main body of the inner capsule into a slender terminal appendix.

The lateral sutures are marked by less prominent ridges, and

FIG. 3.—The same egg as in the preceding figures, from below. Behind is the somewhat irregularly shaped spongy area of attachment.

are continued into one another anteriorly, immediately behind the anterior extremity of the inner capsule. In consequence of the continuity of the lateral sutures, the lower side of the egg can be raised up like a cap or an operculum. The inner capsule is often easily ruptured along the sutures. In the middle line of the lower surface of the inner capsule there is a slight longitudinal groove, and other unimportant grooves often occur. Where the outer capsule is united to the inner capsule there is usually a depression or flattening in the wall of the latter.

[1] "The Oviposition of *Nautilus macromphalus*." By Arthur Willey, D.Sc., Balfour Student of the University of Cambridge. Communicated by Alfred Newton, F.R.S., on behalf of the Managers of the Balfour Fund. Received at the Royal Society February 3. Read February 11, 1897.

The vitellus (Fig. 6) does not fill the entire cavity of the inner capsule, but is surmounted by a layer of colourless, somewhat cloudy, viscid albumen which is massed up, as it were, at the two extremities of the egg. The yolk is of a rich brown colour, of very fluid consistency, and sub-translucent. The surface of

FIG. 4.—Another egg of *N. macromphalus*, seen from above, with the longitudinal slit in the upper wall of the outer capsule widened out so as to expose the inner capsule to view.

the vitellus is quite smooth. The length of the inner capsule is about 26 mm., while that of the enclosed vitellus is 17 mm.

I am not in a position to say much about the embryonic area at present, but I have observed an area pellucida about the

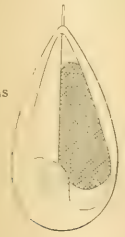

FIG. 5.—Inner capsule of another egg to show the dorsal ridge along the dorsal suture (*d s*) with its anterior terminal prolongation, and the lateral suture (*l s*). *o c*, remains of outer capsule.

middle of the lower surface of the vitellus in an egg which had been allowed to develop for twenty-four hours after being first seen. The large quantity of yolk points to the occurrence of a long period of incubation.

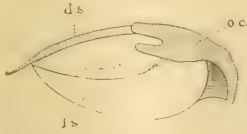

FIG. 6.—The inner capsule of the same egg, seen from below (*i.e.* from the side directed towards the surface of attachment). Half the lower wall of the capsule has been removed by slitting along one of the lateral sutures, and along the median groove (mentioned in the text), to show the brown-coloured vitellus lying in the capsule. The continuity of the lateral sutures in front is well seen. The shaded area represents a depression which occurred in the wall of the inner capsule in the region of the area of attachment of the outer capsule.

Sometimes the capsules of the egg are malformed, and, on opening such an egg, the vitellus is found to be already ruptured.

From the fact that in New Britain I obtained mature males of *Nautilus pompilius*, carrying a spermatophore in the cephalic region throughout the year, I came to the conclusion that the reproduction of nautilus took place all the year round. It now seems probable that the breeding of nautilus, as of so many other forms, is subject to a definite law of periodicity.

Finally, it may be mentioned that *N. macromphalus* varies with regard to the position of the spadix on the right or left side, and also as to the origin of the siphuncular artery, in the same way as *N. pompilius* does. The male of *N. macromphalus* carries a spermatophore in the same position as in *N. pompilius*; and, in fact, the only essential difference between the two species that I know of at present, is the difference between the shells in the umbilical region.

SIXTY YEARS OF SUBMARINE TELEGRAPHY.

SIXTY years in sixty minutes—for thus Prof. Ayrton opened the lecture which he gave on Monday, the 15th inst., at the Imperial Institute. The undertaking seemed arduous, but, in reality, only the pioneer cables were dealt with, since later submarine telegraphy has no history—"Happy is the cable that has no history."

Another difficulty lay in the character of the audience; some were there knowing practically everything about telegraphy, while others were absolutely unfamiliar with the whole subject, except as regards the modern sixpenny wire. Prof. Ayrton, however, by a happy mixture of mathematics and magic lantern, electricity and elocution, seemed to entirely satisfy all classes among his audience.

The lecture opened with a letter of W. F. Cooke's, written in February 1837, in which he mentioned having seen Wheatstone—"a music seller in Conduit-street, but an extraordinary fellow." This acquaintance speedily ripened, for in the same year a partnership was formed between these two men, and the first telegraph line was constructed in this country; they also began to consider the possibility of laying an insulated wire under water.

The actual date of the commencement of subaqueous telegraphy seems, however, to be rather uncertain. Baron Schilling is said to have exploded mines under the Neva by means of an electric current as early as 1812, while it is certain that Colonel Pasley used this method to blow up the wreck of the *Royal George* at Spithead in 1838. But, as Prof. Ayrton pointed out, "it is to Morse that we can with certainty give the credit of having first used a wire under water insulated with india-rubber."

In 1842 this celebrated American inventor, then struggling in most dire poverty, laid with his own hands two miles of india-rubber coated wire between Castle Garden and Governor's Island. In the morning he found his cable broken, but not before he had successfully sent a series of the first subaqueous telegraphic messages.

It was not until after the introduction of gutta-percha into this country that submarine telegraphy became of practical importance. Sir Wm. Siemens first recommended the use of this "wonderful stuff" for insulation purposes, and in 1847 the firm of Siemens and Haske began to coat wires with gutta-percha, by means of a machine on the macaroni principle. Shortly afterwards such cables were laid in the harbour at Kiel and in the Hudson.

The history of submarine telegraphy, from a commercial standpoint, may be said to commence in June 1845, when Jacob Brett registered the General Oceanic Telegraph Company "to form a connecting mode of communication by telegraphic means from the British Islands across the Atlantic Ocean to Nova Scotia and the Canadas, the Colonies, and Continental Kingdoms"—certainly a bold project in those early days. As indicating the electric conditions of those times, the lecturer here quoted an extract from the *Weekly Register*, describing the transmission of the Queen's speech from London to Newcastle in 1847. "The speech was sent by special engine to Rugby, and thence by electric telegraph . . . so that the time occupied in its transmission was the *incredibly* short period of 6½ hours." Certainly, our modern minds do have some difficulty in crediting the time taken in transmission, but it is not due to its amazing shortness.

Meanwhile, Jacob Brett, together with his brother John Watkins Brett, applied to Sir Robert Peel for the purpose of obtaining a telegraphic monopoly; but the answer was unsatisfactory. Two years later the brothers petitioned again, with

greater success, for permission to lay a cable between Dover and Calais. On August 10, 1849, Louis Napoleon granted them an absolute monopoly for ten years, provided that the wire was laid by September 1, 1850. Before this date a telegraph wire under the Channel became an accomplished fact, and messages were certainly transmitted through it, although they seem to have been slightly incoherent. The glory of this telegraph was, unfortunately, short-lived, for after the first evening it maintained an obstinate reserve, and "spoke no more."

The next year another concession was granted to the Bretts by the French Government, and on the strength of this the Submarine Telegraph Company was formed. But £300 was all the public would subscribe, as it had already been conclusively proved that submarine telegraphy was an impossibility. Happily Mr. Crampton came to the rescue, while Mr. Küper suggested armouring the insulated conductor with iron sheathing—a proposal also made by Willoughby Smith. Once more England and France were electrically connected, and on November 13, 1851, the public sent a message through a submarine cable for the first time in the history of the world.

The Bretts then applied to the Government for a monopoly to electrically connect England and Ireland. Prof. Ayrton read out the original replies they received on this occasion, in which each Government department in turn complimented the brothers on their perseverance and success, but regretted that the matter did not lie in their power, and referred them "next door." The laughter that was here heard among the audience was presumably due to the striking contrast this afforded with the promptness and celerity of Government procedure of to-day?

As early as 1844 Morse had written to the American Treasury: "My experience is that telegraphic communication on the electromagnet plan might certainly be established across the Atlantic Ocean." Nothing was done in the matter until 1855, when a syndicate was formed, and in the following year Cyrus Field crossed over to England, where he signed an agreement with J. W. Brett, Charles Bright, and E. Whitehouse to start an Atlantic Telegraph Company.

Great difficulties foreshadowed the working of an Atlantic cable, due to the retardation of the signals. In connection with this subject, the lecturer stated the very different values which had been assigned by Wheatstone, Latimer Clark, and others to the velocity of electricity, before it had been deduced from a paper of Lord Kelvin's, in 1855, that electricity had no velocity in the ordinary sense of the word.

A mechanical model was shown illustrating the difference between the *sudden* opening of a door by a ball projected at it with a certain velocity, and the *gradual* opening of the door by the *gradual* increase of the pull at the other end of a long piece of india-rubber—the latter method being comparable with the action of an electric current. Experiments were also made on a water cable, and it was shown that by combining resistance and capacity, waves of water travelling in opposite directions could exist at the same time in a tube; also that if positive and negative pressures were alternately applied on one end of the tube, with an interval of time less than thirteen seconds between their application, no effect whatever could be detected at the other end of the tube, a distance of seven feet. The spots from three very dead-beat galvanometers, placed respectively at the sending, middle, and receiving end of an artificial Pacific cable, were then projected on the screen, and the gradual rise of current along the cable was made visible to every one, the current at the distant end taking six seconds to reach its steady value.

The lecturer here mentioned Fourier's *Théorie Analytique de la Chaleur*, published in 1822, which "mathematical poem," though written long before cables were dreamt of, enabled Kelvin thirty years later to attack a problem, the successful solution of which has created submarine telegraphy. For two other important conclusions were deduced from Kelvin's 1855 paper, namely, that the time elapsing before the current began to appear at the other end of a cable, only depended on the product of the resistance of the conductor into the electrostatic capacity, and practically not at all on the battery power. Also that the retardation of the signals was proportional to the square of the length. The first of these results was opposed to the opinion of such well-known engineers as Sir Charles, and Edward, Bright, who considered that the velocity of electricity varied with the use of high potential frictional, or of low potential voltaic electricity. From his own theory Kelvin calculated that the probable speed of signalling through the proposed Atlantic cable would be at the rate of three words a minute, which was subsequently found to be obtainable with his mirror galvanometer. Siemens, however, feared that only one word a minute could be sent, while Charles Bright, from experiments on 2000 miles of underground conductor, predicted ten or twelve.

Meanwhile the Atlantic Telegraph Company had been successful in their efforts, for in 1857 the U.S. frigate *Niagara* and H.M.S. *Agamemnon* started from Valentia with 2500 miles of cable coiled in their holds. About a tenth part of this was payed out, and then the wire broke in deep water; and so ended the first attempt to lay an Atlantic cable. The following year a second expedition started, and after several failures this cable was successfully laid, and England first spoke electrically to America. The life of this cable was, however, pitifully short; the signals grew weaker and weaker, and after one little month it died. It was not, indeed, until 1866 that a complete cable was laid by the Telegraph Construction and Maintenance Company, which also in the same year captured a cable that had been previously broken and lost. Thus two good cables were completed between England and America.

Prof. Ayrton then described the siphon recorder in some detail, and exhibited the earliest example of that instrument, constructed in 1870. Later forms were also shown, in which the electrified ink was replaced by the use of a vibrating siphon. The system of automatic sending was explained, and the question of signalling briefly considered, diagrams being thrown on the screen illustrative of the effect of condensers and of curbing in obtaining sharp signals. The word "imperial" was sent by an automatic sender at the rate of seventy-two letters a minute through the artificial Pacific cable in four different ways: (1) with no curbing nor condensers at either end; (2) with curbing only; (3) with condensers only; (4) with curbing and condensers at both ends of the cable.

Before concluding his lecture, Prof. Ayrton, not content with having his subject limited to the space of sixty years, looked ahead and saw, or rather failed to see, the cables of the future. For it is his belief that in the days to come copper conductors, gutta-percha insulation, and iron wire-sheathing will be relegated to the museum of antiquity, and when a person wishes to telegraph to a friend, he knows not where, he will call to him in an electromagnetic voice, which will be heard distinctly by him who has the electromagnetic ear, but will be silent to every one else!

The hall was hung with the portraits of the chief of the early workers in submarine telegraphy, each in its turn being illuminated with a projector when reference was made to it; the lecture was illustrated with historical letters and documents, specimens of all the important early cables, as well as of the latest, hydraulic and other models; and an artificial cable electrically 3600 miles long, fitted up with signalling apparatus at each end, was shown through the kindness of Dr. A. Muirhead.

Mr. Preece was unfortunately absent through illness, but his place as Chairman was filled by Sir Henry Mance. Thus a compensation was afforded in having an opportunity of admiring not Mance's method of finding faults, but his method of finding merits in Prof. Ayrton's sixty years of cable.

THE VALUE OF IRRIGATION CANALS IN INDIA.

THE deplorable state of large districts in India at the present time is attracting a great deal of attention, owing to the famine which is devastating the country, caused by the failure of the crops from the drought and want of rain. Under such conditions, every drop of water is as precious as gold, and the canal authorities have to strain every nerve to make the available water supply spread as far as possible. Any information bearing on the canals cannot fail, at such a time, to be of interest. A return recently issued by the Public Works Department bears testimony not only to the great benefit that has already been conferred on India by the system of irrigation pursued during recent years by the Indian Government, but also shows that these works have been a financial success.

Lord Lansdowne is reported strongly to have urged that public works of irrigation do more good than any other form of public works; and it is a matter of regret that more has not been done in the past in the matter of canal construction. The total area irrigated in India from Government works is about 13½ millions of acres, the estimated value of the crops raised on this area amounting to 37,000,000*l.*, taking a crore of

rupees at 1,000,000*l.*, up to the end of 1895, as far as the report goes. A sum of 20½ millions of pounds had been expended on the construction of 37 works, which brought in a net revenue of 4·32 per cent. on the total capital expended, although some of the works were not then completed. Of these, the Madras canals paid 6·75 per cent. ; the Sind, 6 per cent. ; the North-western Provinces, 5·22 per cent. ; the Punjab, 4·33 per cent. ; Deccan and Goojerat, 1·18 per cent. ; and Bengal, less than one-tenth per cent. The general deductions to be drawn from the figures given in the report are that, while these irrigation canals have been of inestimable value to the productive resources of India, and in mitigating the direful effects of famines, the expenditure has at the same time proved very remunerative ; and that though the Bengal and Bombay canals have been unremunerative, and are never likely to pay, still the works in the other provinces have more than compensated for these losses. The results from minor works, or those constructed out of revenue, are even more satisfactory. Seventy of these works have cost about 3,000,000*l.*, and irrigate 2,194,441 acres, the net revenue yielding 12·61 per cent. on the outlay. The annual allotments for these works have in recent years been 360,000*l.*, of which about 240,000*l.* is expended on up-keep. In view of their remunerative character and immense benefit to the natives, the policy of expending large sums in relief works, and extending the system of irrigation in seasons of drought, as is now being done, must commend itself as being sound legislation. There is a third class of canals, known as "protective" works, the cost of which is charged to the funds set apart for protection from, or the mitigation of, famines. These have cost about 2,000,000*l.* They are principally designed to provide against seasons of drought. Up to the present they have only brought in a return of 1 per cent. on the outlay. They cannot, however, be looked at from a commercial standpoint, but rather on their value in years of drought ; whereas the year to which the return relates was one of considerable rainfall. If, during the present season of drought, they have aided in mitigating the effect that otherwise would have followed in the districts where they are situated, they will have accomplished the object for which they were constructed, although they may not prove commercially productive.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. W. F. Sedgwick, bracketed Senior Wrangler, 1894, has been elected to an Isaac Newton Studentship in Astronomy.

The General Board of Studies has published the proposed regulations for the admission of Advanced Students to certain Triposes. In general the standard to be required from such students is that of a second class in Part ii. of the Tripos. In Natural Sciences a first class in a single subject of Part ii. will be expected.

The Board of Supervision for Indian Civil Service students is about to be formally constituted a Special Board of Studies, with the same status and privileges as the other Special Boards.

Honorary degrees are to be conferred, at the congregation on March 11, on the French Ambassador (Baron de Courcel) and the American Ambassador (Mr. Bayard), and also on Dr. Zahn of Berlin, and Prof. Klein of Göttingen. Dr. Nansen cannot attend on that day, and will accordingly be admitted on March 16.

The following have been appointed Electors to the respective professorships mentioned. Plumian of Astronomy, Prof. H. H. Turner ; Anatomy, Sir W. H. Flower ; Downing of Medicine ; Dr. S. Ringer ; Cavendish of Physics, Prof. A. W. Rücker ; Mechanism and Applied Mechanics, Sir F. J. Bramwell ; Surgery, Prof. Allbutt ; Pathology, Dr. D. MacAlister.

THE Hartley College, Southampton, has received a valuable addition to its library in the form of a complete series of the "*Challenger* Reports," presented by the Government at the representation of the Royal Society.

AT a meeting of the London County Council on Tuesday, the recommendation of the Technical Education Board, asking the Council for the sum of £150,000 from the Customs and Excise dues, for the purpose of technical education in London during the year 1897–98, was agreed to.

AT the last meeting of the Council of Bedford College, London, the following resolution was passed unanimously : "That the Council and Teaching Staff of Bedford College, London, express the earnest hope that Her Majesty's Government will at an early date again introduce a Bill for the creation of a Statutory Commission for the reconstitution of the University of London on the lines indicated by Lord Cowper's Commission, and assure the Government that such a measure will have their active support."

Science announces the following gifts to education in the United States :—The will of the late Mrs. Horatio Lyon, of Springfield, Mass., gives, among other public bequests, 10,000 dols. to Monson Academy, 10,000 dols. to Pomona College, and 10,000 dols. to Menden Free Library.—Harvard University has received from Mr. J. Howard Nichols 5000 dols. to be used to found a new scholarship, preference being given to a student from the State of Alabama.—The will of the late Charles Willard, of Battle Creek, Mich., leaves 40,000 dols. to the Baptist College at Kalamazoo, Mich., and 40,000 dols. for a library building for the city schools at Battle Creek, Mich.

WE are glad to see that the University colleges are to be given an additional grant by the Government. The increase was announced in the House of Commons on Monday, when Sir W. Houldsworth (Manchester, N.W.) asked the Chancellor of the Exchequer whether any report had yet been received from the Commissioners appointed by him to visit the University colleges which received a Government grant, and, if so, whether there was any prospect of these colleges, or any of them, receiving an augmented grant in the next financial year. The Chancellor of the Exchequer replied to the first question in the affirmative, and he pointed out that an additional grant of £9500 for the University Colleges appears in the Civil Service Estimates.

THE *Journal of School Geography*, the first number of which has just been published at Lancaster, Pennsylvania, U.S.A., should be a real source of help and a valuable geographical aid to teachers in elementary and secondary schools. The aim of the new periodical is to present the newest and best geographical information in such a form that it can be readily used for teaching purposes. The responsible editor is Prof. Richard E. Dodge, Teachers' College, New York City, and associated with him are Prof. W. M. Davis, Mr. C. W. Hayes, Prof. H. B. Kummel, Dean McMurry, and Mr. R. de C. Ward. Natural science, physical geography, geology, physiography, pedagogy, and climatology are thus all represented upon the editorial staff, so that attention to all the phases of the broad science of geography is ensured. The new journal should be of great assistance in advancing geographical knowledge, and in making the study of the earth a means of developing the habit of observation.

THE following are among recent appointments :—Prof. Francis E. Lloyd to be professor of biology in the Teachers' College, New York ; Dr. Alexander P. Anderson to be professor of botany at Clemson College, S.C. ; Postmaster-General Mr. L. Wilson to be president of the Washington and Lee University at Lexington, Kentucky ; Dr. Chr. Nussbaum to be professor of hygiene in the Technical High School at Hanover ; Dr E. Wiechert, privat-docent in mathematical physics at Königsberg, to be titular professor ; Dr. J. Liznar to be professor of meteorology at Vienna ; Hon. James Wilson, director of the Iowa Agricultural Station and professor of agriculture in the Iowa Agricultural College, to be Secretary of Agriculture in the United States ; Dr. L. A. Bauer to be assistant professor of mathematics and mathematical physics in the University of Cincinnati ; Dr. L. F. Barker to be assistant professor of anatomy in the Johns Hopkins University (Baltimore).

IN a valuable and well-considered report upon the work accomplished last year, under the auspices of the Technical Education Committee of the Derbyshire County Council, Mr. Percy Hawkridge shows that in his county a very great development of classes for industrial students has taken place since the advent of the County Council into the educational field. In 1890-91 there were 700 students attending elementary science classes in Derbyshire ; in 1891–92, when the County Council education scheme came into force, there were 1325 students ; and in 1894–95 the number was 2342. This great development has taken place although classes not connected with local

industries have been almost entirely weeded out, and in spite of the raising of the standard in the Government examinations. It is worth noticing that prior to 1891, not more than 20 students attended mining classes, although there are over 150,000 people dependent on this industry. There are now close upon 600 such students. Mr. Hawkridge also points out that in 1891, after the Science and Art Department had been in existence for over 25 years, less than 100 pupils of secondary schools in Derbyshire were receiving instruction in science, which instruction was wholly theoretical in character. There are now 500 pupils under scientific instruction *in properly equipped class-rooms and laboratories*. This is a point the importance of which it is almost impossible to over-estimate. The facts are held to indicate that local authorities, being more intimately in touch with local needs and circumstances than any central body, are better able to develop educational work in the right direction. Mr. Hawkridge hopes, therefore, that so far as secondary and technical education are concerned, future legislation and future administrative changes may tend to place the details of local management more completely and unreservedly in the hands of responsible and representative local authorities.

SCIENTIFIC SERIALS.

In a continuation of the important paper, in the *Journal of Botany* for January, on Welwitsch's African Freshwater Algæ, W. and G. S. West describe no less than three new genera—*Psephotaxus*, belonging to the Ulotrichaceæ; *Tetmogametum*, the type of a new family of Conjugatæ; and *Pyxispora*, belonging to the Zygnemaceæ.

The number of the *Nuovo Giornale Botanico Italiano* for January contains the commencement of a *Prodromus* of the mosses of Bolivia, by Sig. K. Müller; an account of the ferns and fern-allies collected by Father Giraldi in China, by Sigg. Baroni and Christ; and a description, by Sig. Massolongo, of the galls produced on *Stipa pennata* by *Tarsonemus Canestrinii*.

In a batch of the *Bullettino* of the Italian Botanical Society, which has just reached us (October 1896 to January 1897), are a very large number of papers of special interest to Italian botanists. In addition, Sig. A. Jatta discusses at length Minks's theory of symbiosis in lichens. While admitting the importance of the facts brought forward by Minks, he does not consider that these militate against the theory of the parasitism of lichens. Prof. L. Macchiati describes the microbe which produces flaccidity in silkworms. Prof. Arcangeli discusses the cause of the presence or absence of the black spots on the leaves of *Arum italicum*, which may be connected with the attraction of insects for the purpose of fertilisation. Prof. Macchiati has a further note on the vexed question of the endosperm in the seeds of *Vicia narbonensis*.

American Journal of Science, February.—Outlines of a natural classification of the Trilobites, by C. E. Beecher. The present state of knowledge of their structure and development is in favour of giving the trilobites the rank of a sub-class, but for purposes of comparison and correlation the fullest results can be brought out by recognising the old and well-known sub-classes, the Entomostraca and Malacostraca. This gives three divisions of Crustacea, and the trilobites agree closely with the theoretical crustacean ancestors of the other sub-classes. The author gives a complete diagnosis of the Trilobita, and intends in a subsequent paper to give a classification based upon their ontogeny.—Preliminary trial of an interferential induction balance, by C. Barus. The slender iron cores of two identical helices are placed at right angles to each other in a horizontal plane, and at the same distance from their point of convergence. The distant ends are rigidly fastened, and the fore ends are provided with small plane mirrors. The latter form part of a Michelson refractometer system. Interference fringes may be produced when the apparatus is at rest, or the two mirrors vibrate in an identical manner. They vanish when the plane is displaced. This apparatus is capable of many useful applications to alternating currents and magnetic induction.—The multiple spectra of gases, by J. Trowbridge and T. W. Richards. The difference between the red spectrum of argon obtained with a steady current from a high-potential accumulator and the blue spectrum obtained by means of undamped oscillations has its counterpart in nearly all the other elementary gases. The fluted spectrum of nitrogen is obtained by the steady discharge, and the line spectrum by the condenser. Hydrogen in the former case gives a band spectrum resolvable into sharp lines. Similar differences are observed in the spectra of the halogens. They may, however, be simply due to a change of temperature. Further experiments are being made to decide this point.—Nocturnal protective colourations in animals as developed by natural selection, by A. E. Verrill (will be printed in full).—The Stylinodontia, a sub-order of Eocene Edentates, by O. C. Marsh.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 4.—"The Gaseous Constituents of certain Mineral Substances and Natural Waters." By William Ramsay, F.R.S., and Morris W. Travers, B.Sc.

Helium was found to be present in the gases evolved on heating fergusonite, monazite, samarskite, columbite, and pitchblende.

In malacone (a specimen from Hitterö, collected by one of the authors) both argon and helium were found. This is remarkable as being the only case of a mineral yielding argon. The result was twice confirmed.

The following minerals gave carbon monoxide:—Cinnabar and cryolite.

The following gave a mixture of hydrogen and carbon monoxide:—Apatite; also blue clay from the Kimberley diamond-fields.

The following gave hydrogen alone:—Serpentine, gneiss.

The following gave no gas:—Baryta, celestine, and scapolite.

Five meteorites were examined; only hydrogen was evolved.

A previously examined specimen gave both argon and helium.

The sulphur wells of of Harrogate and of Strathpeffer gave argon but no helium.

The mineral waters of Cauterets, Pyrenees, gave both argon and helium. The spectra of these samples of gas were carefully examined in the hope of finding evidence of some new substance, but without result. If a new substance is present, it cannot exist in measurable quantity in any of the samples examined.

February 11.—"The Artificial Insemination of Mammals and subsequent possible Fertilisation or Impregnation of their Ova." By Walter Heape, M.A., Trinity College, Cambridge. Received January 15.

Chemical Society, February 4.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—Observations upon the oxidation of nitrogen gas, by Lord Rayleigh. It is doubtful whether Davy's statements respecting the oxidation of dissolved nitrogen in water during electrolysis are correct. A detailed account is given of the apparatus used in oxidising nitrogen by an electric arc; the apparatus causes 21 litres of the mixed gases to combine per hour at an expenditure of 1 horse-power. The influence of pressure upon the oxidation of nitrogen was also studied.—On some apparatus for steam-distillation, by F. E. Matthews.—Researches in the stilbene series, I., by J. J. Sudborough. Small quantities of benzil are formed on heating benzoïn with acetic acid. Deoxybenzoïn is converted into a solid chlorostilbene by phosphorus pentachloride; similarly methyl- and ethyl-deoxybenzoïn yields methyl- and ethyl-chlorostilbene. Diortho-substituted benzoic acids. III. Hydrolysis of substituted benzamides, by J. J. Sudborough, P. G. Jackson, and L. L. Lloyd. In order to determine whether diortho-substituted benzamides exhibit a similar degree of stability towards hydrolysing agents as do the diortho-benzoyl chlorides, a number of substituted benzamides have been examined.—Conversion of campheroxime into methylcamphorimine and camphenylnitramine, by M. O. Forster. The base which the author has obtained by heating camphoroxime with methylic iodide is methylcamphorimine,

—Note on Wechsler's method for the separation of fatty acids, by A. W. Crossley. The author finds that Wechsler's process for separating fatty acids by partially neutralising and steam distilling the mixture is unsatisfactory.—On the crystalline structure of gold and platinum nuggets and gold ingots, by A. Liversidge. The author suggests, as the result of experiment, that the gold in nuggets has been slowly deposited from solution,

the nuggets being more or less rolled masses of gold which have been set free from disintegrated veins.—On the presence of gold in natural saline deposits and marine plants, by A. Liversidge. Rock salt, sylvine, and other similar saline deposits, bittern, seaweed, kelp, oyster-shells, &c., have been examined for gold; the natural salts contained from 1 to 2 grains of gold per ton, whilst kelp and bittern furnished up to 20 grains of gold per ton.

Geological Society, February 3.—Dr. Henry Hicks, F.R.S., President, in the chair.—The subgenera *Petalograptus* and *Cephalograptus*, by Miss G. L. Elles. The forms referred to in the paper are accepted as subgenera of *Diplograptus*, as defined by Lapworth. The two subgenera have frequently been much confused, but examination of specimens preserved in relief shows that they have very distinctive characters, especially at the proximal ends. The author gave diagnoses of the two subgenera, and detailed descriptions of certain forms.—On some superficial deposits in Cutch, by the Rev. J. F. Blake. The author arranges the deposits of which he treats under the following heads: (1) Sub-recent Concrete; (2) Boulder Beds associated with the former; (3) Quartzite Reefs; (4) Infratrappean Grits; (5) Laterite; (6) Alluvium and Rann. In the discussion which followed, Dr. W. T. Blanford expressed his satisfaction that some of the peculiar formations of Western India had been examined by an English geologist of experience.

Mathematical Society, February 11. — Prof. Elliott, F.R.S., President, in the chair.—Mr. F. S. Macaulay read a paper on a theorem in non-Euclidean geometry. An animated discussion followed, in which the President, Mr. Kempe, F.R.S., Mr. Love, F.R.S., and Lieut.-Colonel Cunningham, R.E., joined with the author.—Mr. Kempe made an impromptu communication on Prof. Sylvester's partition theorem, and the President and Major MacMahon, R.A., F.R.S., also spoke on the subject. The President (Major MacMahon, Vice-President, in the chair) gave a short account of Mr. Segar's theorem, that the product of the differences of n unequal numbers is divisible by the products of the differences of 0, 1, 2, 3, . . . $(n-1)$, and showed, also, that the product of the differences of n unequal square numbers is divisible by the product of the differences of $0^2, 1^2, 2^2, 3^2, \ldots (n-1)^2$.—Lieut.-Colonel Cunningham brought forward some high primes. They were forty-three in number, the highest being 25,621,901, and the lowest 9,170,881.—A paper by Mr. H. M. Taylor, on the degeneration of a cubic curve, was communicated by reading its title.

Zoological Society, February 16.—Prof. George B. Howes in the chair.—Dr. E. C. Stirling, F.R.S., exhibited some bones, casts, and photographs of the large extinct struthious bird from the *Diprotodon*-beds at Lake Callabonna, South Australia, which had been recently discovered and named by him *Genyornis newtoni*, and gave a history of the principal facts connected with its discovery.—Mr. G. E. H. Barrett-Hamilton exhibited a pair of Walrus-tusks from the Pacific, belonging to the species which has been named *Trichechus obesus*, and gave some account of the Cetaceans and Seals of the North Pacific.—Mr. A. Smith Woodward read a description of *Echidnocephalus troscheli*, an extinct fish from the Upper Cretaceous of Westphalia, proving its identity in all essential respects with the existing deep-sea genus *Halosaurus*.—Mr. G. A. Boulenger, F.R.S., read a note on *Acanthocybium solandri*, which recorded the occurrence of this fish in the Arabian Sea. A specimen of it, transmitted by Surgeon Lieut.-Colonel Jayakar, from Muscat, had recently been received by the British Museum, in which the species had been previously represented only by a dried head from the Atlantic.—Mr. W. E. de Winton made some remarks on the distribution of the Giraffe, and gave the synonyms and more definite descriptions of the two existing forms. *Giraffa camelopardalis*, Linn., was fixed for the name of the three-horned northern form, and *G. capensis*, Less., for that of the two-horned southern species. —A communication was read from Dr. Alfred Dugès containing a description of a new Ophidian from Mexico, which was proposed to be named *Oreophis boulengeri*. gen. et sp. nov.—A communication was read from Mr. C. Davies Sherborn, containing a list of the exact dates of the publication of the parts of the natural history portion of Savigny's "Description de l'Egypte."—Mr. F. E. Beddard, F.R.S., read a paper on the anatomy of the Tropic-bird (*Phaethon*) of the order Steganopodes, amongst which he considered it to occupy a low position near *Fregata*.

Royal Meteorological Society, February 17.—Mr. Edward Mawley, President, read a report on the phenological observations during the past year.—The Hon. Rollo Russell gave the results of some observations on haze and transparency which he had made at Haslemere, in Surrey. From these it appears that the clearest hours, at a good distance from towns, are from about noon to 3 p.m. The clearest winds are from S. to N.W. inclusive, and especially W.S.W., W., and W.N.W.; the haziest are those between N. and E. On bright mornings with a gentle breeze or calm, from autumn to spring, the haze or fog which has lain on the low ground frequently covers the hills in the course of its ascent a few hours after sunrise. At any distance within 100 miles of London, or of the Black Country, observations requiring clear views are likely to be interfered with when the wind blows from their direction, and should, therefore, be taken early.

PARIS.

Academy of Sciences, February 15.—M. A. Chatin in the chair.—The election of M. Sebert in the Section of Mechanics was confirmed by the President of the Republic.—Notice on the life and works of General Favé, by M. Sarrou.—Note on the third part of the "Catalogue of the Paris Observatory," by M. Lœwy.—The age of copper in Chaldea, by M. Berthelot. The analysis of a spear, carrying drawings and inscriptions, and at least 4000 years old, showed that the metal was nearly pure copper, neither tin, lead, arsenic, nor antimony being present in appreciable quantities. The oxidised portion was nearly pure atakamite, $3CuO.CuCl_2 + 4H_2O$. The description of these and similar objects as bronze is thus shown to be erroneous. Copper appears to have preceded bronze in the manufacture of tools.—Studies on the methods of manufacturing wine in the southern regions, by M. A. Muntz. If the temperature during fermentation is allowed to rise to 40° or thereabouts, as will frequently be the case in the southern districts, the yeast is killed, fermentation is stopped, and the conditions are then favourable for the growth of bacteria prejudicial to the wine. At the same time considerable quantities of ammonia salts are produced. These ill-effects can be prevented by artificial cooling with water, in an apparatus nearly identical with that used for cooling beer worts. The most favourable temperature at which to commence cooling is about 34°.—On certain points in the theory of residues of powers. Distinctive characters of numbers or roots from which arise generating residues, by M. de Jonquières.—On the planet Mars, by M. Perrotin. An account of observations on Mars made chiefly during December last, with the large equatorial at the Observatory of Meudon (see p. 401)—Remarks on the preceding note, by M. J. Janssen.—Description of some air barometers, allowing of the measurement of atmospheric pressure with a higher accuracy than with the mercury barometer, by M. V. Ducla. A description of a navigable aerostat, by M. Dheutte.—On operations in general, by M. C. Bourlet.—On a series of primitive groups, isomorphic holohedrically to multiple transitive groups, by M. Ed. Maillet.—On a safe receiver for containing liquefied gases, by M. J. Fournier.—A self-recording apparatus for measuring the movements of the pendulum, by MM. Jean and Louis Lecarme.—Changes of colour in flashes of light of short duration, by M. Aug. Charpentier. For short periods, other things being equal, the less refrangible colours are the first seen. When the intensity diminishes the more refrangible colours predominate, according to the law of Purkinje.—On the influence of the Röntgen rays upon the explosive distance of the electric spark, by M. Guggenheimer. The experiments showed that keeping the sparking distance and potential difference constant, the increase of the explosive distance depends upon the intensity of the Röntgen rays falling upon the spark gap. If the potential and intensity of the rays were kept constant, the increase of the explosive distance depends upon the distance of the spark gap from the emissive wall of the tube.—On the false equilibrium of hydrogen selenide, by M. H. Pelabon.—Action of cuprous oxide upon solutions of silver nitrate, by M. Paul Sabatier. The silver is removed from solution, a greyish deposit being formed, which, upon a careful examination, was found to consist of a mixture of metallic silver and basic copper nitrate.—Action of the oxides of nitrogen upon ferrous chloride and bromide, by M. V. Thomas.—On some derivatives of salicylic aldehyde, by M. Paul Rivals.—On a vegetable lipase extracted from *Penicillium glaucum*, by M. E. Gérard. Cultures of this mould have the property of saponifying monobutyrin,

nd hence contain a ferment either identical or closely analogous to the lipase of M. Hanriot. — Influence of diet and starvation on the effects of certain microbial toxines, by MM. J. Teissier and L. Guinard. The effects of the toxines of diphtheria and pneumobacilline are considerably modified by the absence of nourishment. The experiments have not yet been sufficient to warrant general conclusions, but the tendency of those described has been to show that the lesions produced by the toxines are much less severe in the absence of food.—New observations on the Lepidoptera harmful to maize and sugar-cane. The autumn-winter generations of *Sesamia monogrioides*, Lefèvre, by M. J. Kunckel d'Herculais.—Morphology of the appendices of the anterior extremity of the middle intestine of the Orthoptera, by M. L. Bordas.—Phenomena of autotomy in *Monandroptera* and *Raphiderus*, by M. Edmond Bordage.—On the Diatoms contained in the calcium phosphate deposits in the south of Tunis, by M. J. Tempère.—Lithological analysis of the sea-bottom in the Bay of Biscay, by M. J. Thoulet.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 25.

ROYAL SOCIETY, at 4.30.—Note on the Dielectric Constant of Ice and Alcohol at very Low Temperatures: Prof. Dewar, F.R.S., and Prof. Fleming, F.R.S.—On the Relation between Magnetic Stress and Magnetic Deformation in Nickel: Dr. E. T. Jones.—On the Relations between the Cerebellar and other Centres (namely, Cerebral and Spinal), with especial reference to the Action of Antagonistic Muscles (Preliminary Account): Dr. Max Löwenthal and Prof. Horsley, F.R.S.—On the Action of Light on Diastase, and its Biological Significance: Prof J. R. Green, F.R.S.—Fragmentation in *Linum gessereusis*: A. Brown.

ROYAL INSTITUTION, at 3.—The Problems of Arctic Geology: Dr. J. W. Gregory.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Electric Interlocking the Block and Mechanical Signals on Railways: Reply of F. T. Hollins to the Discussion.—Relative Size, Weight, and Price of Dynamo-electric Machines: E. Wilson.

SANITARY INSTITUTE, at 8.—Sanitary Laws and Regulations governing the Metropolis: A. Wynter Blyth.

CAMERA CLUB, at 8.15.—Silchester, the Result of Recent Explorations: H. Jones.

FRIDAY, FEBRUARY 26.

ROYAL INSTITUTION, at 9.—Palestine Exploration: Lieut.-Colonel C. R. Conder.

PHYSICAL SOCIETY, at 5.—On the Photography of Ripples: J. H. Vincent.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Rockers and Expansion-Bearings as applied to Girders of Short Span: A. F. Baynham and F. B. H. Debree.

SATURDAY, FEBRUARY 27.

ROYAL INSTITUTION, at 3.—The Growth of the Mediterranean Route to the East: W Frewen Lord.

ROYAL BOTANIC SOCIETY, at 3.45.—The Desirability of establishing an Institute for Teaching Botany in the Royal Botanic Gardens: W. Martindale.

MONDAY, MARCH 1.

SOCIETY OF ARTS, at 8.—The Industrial Uses of Cellulose: C. F. Cross.

IMPERIAL INSTITUTE, at 8.30.—Ceylon, in Ancient and Modern Times: Henry W. Cave.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Relation of Colour to Quality in Malt: J. W. Lovibond.—Hehner's Bromine Tests for Oils: J. H. B. Jenkins.—Note on the Analysis of Superphosphates: J. H. Coste.

SANITARY INSTITUTE, at 8.—Nature of Nuisances: Dr. Arthur Newsholme.

VICTORIA INSTITUTE, at 4.30.—Science and Faith: Prof. MacLoskie.

TUESDAY, MARCH 2.

ROYAL INSTITUTION, at 3.—Animal Electricity: Prof. A. D. Waller, F.R.S.

SOCIETY OF ARTS, at 8.—Gesso: Matthew Webb.

ZOOLOGICAL SOCIETY, at 8.30.—The Growth of Hair upon the Human Ear, and its Testimony to the Shape, Size, and Position of the Ancestral Organ: H. M. Wallis.—Notes on a Visit to the Bird Islands, Saldahna Bay, South Africa (illustrated with Photographs from Life shown by Lime-light): Gambier Bolton.—On a Collection of Earthworms from South Africa, belonging to the Genus *Acanthodrilus*: F. E. Beddard, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Papers to be further discussed: The Main Drainage of London: J. E. Worth and W. Santo Crimp.—The Purification of the Thames: W. J. Dibdin.

PATHOLOGICAL SOCIETY, at 8.30.

ROYAL VICTORIA HALL, at 8.30.—A Lump of Salt: Prof. Holland Crompton.

WEDNESDAY, MARCH 3.

SOCIETY OF ARTS, at 8.—English Orchards: George Gordon.

ENTOMOLOGICAL SOCIETY, at 8.—The Prothoracic Gland of *Dicranura vinula*: O. H. Latter.

THURSDAY, MARCH 4.

ROYAL SOCIETY, at 4 30.—*Probable* Papers: Experiments on the Absence of Mechanical Connection between Ether and Matter: Prof. Lodge, F.R.S.—Second Report on a Series of Specimens of the Deposits of the Nile Delta. Communicated by desire of the Delta Committee: Prof. Judd, F.R.S.—Luminosity and Photometry: Prof. J. B. Hayeraft.

ROYAL INSTITUTION, at 3.—Greek History and Extant Monuments: Prof. Percy Gardner.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

LINNEAN SOCIETY, at 8.—On a Trichoderma parasitic on *Pellia epiphylla*, Corda: W. G. P. Ellis.—New Species of Perichæta from New Britain, &c.: Dr. W. B. Benham.

CHEMICAL SOCIETY, at 8.

SANITARY INSTITUTE, at 8.—Objects and Methods of Inspection: Dr. J. F. J. Sykes.

CAMERA CLUB, at 8.15. Captain Abney, C.B., F.R.S.

FRIDAY, MARCH 5.

ROYAL INSTITUTION, at 9.—Some Curiosities of Vision: Shelford Bidwell, F.R.S.

GEOLOGISTS' ASSOCIATION, at 8.—Some Properties of Precious Stones: Prof. Henry A. Miers, F.R.S.

SATURDAY, MARCH 6.

ROYAL INSTITUTION, at 3.—Electricity and Electrical Vibrations: Lord Rayleigh.

ESSEX FIELD CLUB, (at Buckhurst Hill), at 7.—The Post-Pliocene Non-Marine Mollusca of Essex: A. S. Kennard and B. B. Woodward.—Variation of Lepidoptera: J. W. Tutt.

BOOKS, PAMPHLET, and SERIALS RECEIVED.

BOOKS.—Life Assurance Explained: W. Schooling (Cassell).—Pheasants, their Natural History and Practical Management: W. B. Tegetmeier, 3rd edition (Cox).—New Thoughts on Current Subjects: Rev. J. A. Dewe (Stock).—Retaining Walls for Earth: Prof. M. A. Howe, 3rd edition (New York, Wiley; London, Chapman).—Principles of Mechanism: Dr. S. W. Robinson (New York, Wiley; London, Chapman).—The Mechanical Engineering of Power Plants: Prof. F. R. Hutton (New York, Wiley; London, Chapman).—Notes on Assaying: Drs. Ricketts and Miller (New York, Wiley; London, Chapman).—The Dawn of Modern Geography: C. R. Beazley (Murray).—Metals, their Properties and Treatment: Prof. A. K. Huntington and W. G. McMillan, new edition (Longmans).

PAMPHLET.—Société d'Encouragement pour l'Industrie Nationale. Annuaire 1897 (Paris).

SERIALS.—Contributions from the U.S. National Herbarium, Vol. v. No. 1 (Washington).—Proceedings of the Physical Society of London, Vol. xv. Part 2 (Taylor).—The Open Court, February (Chicago; London, Watts).—Fresenius' Quantitative Analysis, Vol. ii Part 4, translated by C. E. Groves (Churchill).—Lloyd's Natural History, Game Birds: W. R. Ogilvie-Grant. Parts 4, 5, 6. Ditto, Monkeys: Dr. H. O. Forbes. Part 6 (Lloyd).—Bulletin de l'Académie Royale des Sciences, &c., de Belgique. 1897, No. 1 (Bruxelles).—Records of the Australian Museum, Vol. iii. No. 1 (Sydney).

THE NEED OF ORGANISING SCIENTIFIC OPINION.

I.

"Dear Sir,—You wish to know my notions
On sartin pints thet rile the land;
There's nothin' that my natur' so shuns
Ez bein' mean or underhand;
I'm a straight-spoken kind o' creetur
Thet blurts right out wut's in his head."

"There is a point where toleration sinks into sheer baseness and poltroonery. The toleration of the worst leads us to look on what is barely better as good enough, and to worship what is only moderately good. Woe to that man, or that nation, to whom mediocrity has become an ideal!"

LOWELL: "Biglow Papers."

"When a nation is unhappy, the old Prophet was right and not wrong in saying: Ye have forgotten God, ye have quitted the ways of God, or ye would not have been unhappy. It is not according to the laws of Fact that ye have lived and guided yourselves, but according to the laws of Delusion, Imposture and wilful and unwilful *Mistake* of Fact. We must have more Wisdom to govern us, we must be governed by the wisest, we must have an Aristocracy of Talent . . . but how to get it? . . . done nevertheless, sure enough, it must be; it shall and will be." CARLYLE: "Past and Present."

MR. WILLIAMS'S little book, "Made in Germany," has considerably "riled the land," for, as most will know, it has attracted much notice. Shortly after its appearance, Lord Rosebery took it under his immediate protection, and discoursed upon it in public in a most interesting manner; and the fashion being thus set, many other politicians directly or indirectly referred to it. The Press throughout the country has contained articles innumerable discussing more or less superficially the issues which it raises. A rival volume has been published, under the title "The German Bogey," to refute, if not its conclusions, its recommendations. Last, but not least, it has pricked even the departmental conscience; and so great did the scare become, that the President of the Board of Trade felt justified, as he has lately told us, in ordering an inquiry into the matter. If report do not belie them, Sir Courtenay Boyle and Sir Robert Giffen entered on the inquiry with the desire and with the conviction that they would be able by the elastic agency of statistics to burst the big bubble blown in public by Mr. Williams; and if this be really the case, the very guarded tone of their Report is particularly noteworthy. Whatever desire they may have had to curse, if they do not bless, they at least show no cause why fault should be found with his implied main contention—which is, not merely that we are being beaten in this or that direction by commercial rivals, but that we are fast proving ourselves incapable of understanding the altered conditions under which the world now works, and of acting in accordance with such altered conditions.

Although the attention of the British public must have been in some degree attracted by all this cackling, yet there is no reason to suppose that the effect will be otherwise than ephemeral. It is clearly impossible to properly awaken John Bull from his stupid easy state of inordinate self-complacency, and whatever uneasiness he may feel for a time, he is soon reassured by comfortable optimism such as that displayed by political speakers like Lord Herschell and Mr. Ritchie in their recent addresses on foreign competition and trade, and when told that the fiscal returns show that business is improving, and that after all we are not doing so badly.

In fact, although ill at ease, the nation is incapable of appreciating the true depth and nature of its "unhappiness." Few of those who have criticised Mr. Williams, or even of those who have applied his arguments, are capable of fully understanding their force; the condition which he diagnoses as existing throughout the country must be judged by criteria other than those which mere statistics afford, or which are patent to politicians and the present race of statesmen.

Nothing could be further from the truth than a statement such as that recently made in the *Times* that it is too often forgotten that foreign countries are simply making up leeway. German industry is developing and prospering because it is conducted by methods almost exclusively forged in Germany, and which she alone of all nations knows how to use systematically, regularly and generally; because she has learnt how to organise and to discipline and to properly officer her forces; not because she has paid attention to "technical" education—but because she alone has known how to organise a true system of education, and has introduced a valid discipline into her schools; in short, because the nation has enjoyed a *scientific* education during practically the whole of the century, and is in consequence a cultured nation.

The story told by Sir Philip Magnus and his colleagues, in their interesting and most valuable letter to the Duke of Devonshire, contains absolutely no element of novelty: we merely see from it that we have to congratulate Germany on her continued attention to the advice and guidance of that "Aristocracy of Talent" which only she, of all nations of the world, has seen fit to create, to encourage and to properly utilise.

But we are not alone in our despondency. France, equally with ourselves, is alarmed at and envious of the success of Germany; her position is singularly similar to our own, as she also suffers from the want of a true national ideal of education. That two peoples such as the French and the English should lapse into such a state of flutter, however, is more than passing strange, and betokens great uneasiness of conscience, as we cannot either of us possibly imagine that we are to be left alone to manufacture for the world, or that those whom circumstances have so long unfortunately prevented from contributing their fair share are for ever to be kept under.

The ungenerous character of our complaints against articles made in Germany ought to be more obvious to us than it clearly is at the moment; to say the least, it is disgraceful that we should use the selfish arguments we do, in order to rouse a feeling of responsibility in our country, especially as we thereby withdraw attention from the true nature of the evil. Germany has but done her duty and lived according to the laws of Fact, and guided herself thereby; whilst we have followed the laws of Delusion, Imposture, and wilful and unwilful *Mistake* of Fact—for however unpleasant Carlyle's pessimism may be, it is impossible to deny the relevance of his conclusions to the present situation.

Let us, then, awaken to a sense of our duty, and to a sense of the real source of the danger which not only

menaces us, but by which we are already, in part, overcome. In the future, we have to fear not German competition but that of our own colonists beyond the seas, and perhaps that of our American cousins most of all, besides that of the cheap labour of the vast populations of climes where Europeans cannot work with advantage. It is folly to suppose that Lancashire can continue much longer to spin cotton for the world; but America, Egypt, India, Japan and, sooner or later, China also will deprive us of the trade—not Germany, for she will suffer proportionally with ourselves.

It is all very well to congratulate ourselves on a temporary improvement in our iron trade, and to argue that an increase of a few per cent. in our output is more than equal to the whole output of a country which, may be, is advancing its production at a far greater rate than we are; but it cannot be forgotten that we largely import our iron ores, that fuel is got with increasing difficulty, and that wages are likely to rise considerably. In America, on the other hand, wages are likely to fall rather than rise, and ores and fuel are to hand in inexhaustible quantities, so that it cannot be long ere American iron will successfully compete with English and foreign.[1] In a Trade Review Circular before me, I find the words:—"Tin-plates: The majority of the orders primarily came from the United States, but every day brings us further proof that the time is not far distant when this will almost disappear." We must recognise that, at no very distant date, this will have to be said of articles of far greater importance than tin-plates. It is well known that shipbuilding, long a staple industry of this country, is fast being developed, not only in Germany, but also in the United States. America is bound, in fact, to develop, and not only on account of the restless energy of her people: her Government departments have attached to them many active men engaged in initiating or conducting scientific inquiries; and when the various departments are organised *inter se*, the country will have in its service a highly-trained body of scientific experts guiding all branches of public work, and cooperating to minimise the faults of democracy. And universities are arising all over the country, in which German models are being followed, not English. It is safe to predict that, ere many years are past, the United States will suddenly burst into prominence, and probably into predominance, as a nation promoting scientific inquiries of all kinds, so surely is a foundation being laid. Mistakes will frequently be made, perhaps, but they will soon be recognised and remedied in a country instinct with advance.

It is useless to consider mere statistics and to contrast the money values of our imports and exports; we must consider rather the extent to which our established industries have developed in response to modern requirements, and the extent to which new industries have been developed. When this is done, it is difficult—nay, impossible—to resist the conclusion that we are becoming less and less capable of helping ourselves, and more and more the victims of chance. In the engineering trades, which have always necessarily been conducted on fairly scientific lines, being based on exact measurements, we can still hold up our heads—as witness the marvellous development of the cycle industry. But in most, if not all those in which chemistry indirectly or directly plays a part—and in which does it not?—we are daily getting more and more behind the times: the research spirit practically does not enter into our industries; scientific method has no real place in most of them. The few brilliant exceptions which may be quoted but serve to prove this rule. But these are points which entirely escape Board of Trade officials and politicians and the general public; only those who have to do with our manufacturers are aware how entirely conservative and unprogressive are their views and actions.

In English works, as a rule, the sole effective management rests with the capitalist and man of business. This class of man places himself entirely in the hands of his works-manager or foreman, whose doings he too often cannot in the least criticise; and, consequently, a commanding position is taken in this country by the so-called practical man—one who knows how to do one thing, perhaps, very well, but being without scientific training and theoretical knowledge cannot advance, and if things do not go on as they should, is at a loss to know what exactly is wrong. And such men, unfortunately, are doing their very utmost, even at the present day, to prevent the entry into works of those who, having been scientifically trained, are capable of investigating the processes in charge of which they are placed, as well as of devising improvements and of preventing waste.

How different is the state of affairs elsewhere. To quote evidence given before the Sub-Committee of the London Technical Education Board by Dr. Messel, a well-known English manufacturer conversant with both the foreign and our system, not only is the importance of science far more acknowledged by manufacturers abroad than it is here, but it is accorded a consulting and deliberating voice in the management of their industries; furthermore, at the head of affairs you mostly find people who, however little they may now be able to devote themselves to scientific pursuits, possess a thorough scientific education, which befits them to select such scientific assistance (in chemistry, engineering, construction, &c.) as their work may require, who are capable of appreciating it, and who remain in touch with scientific teachers' teaching and progress.

As Matthew Arnold wrote in 1874, in the preface to the second edition of his "Higher Schools and Universities in Germany": "German practice is governed by the notion that what is to be done, should be done *scientifically*, as they say; that is, according to the reason of the thing, under the direction of experts, and without suffering ignorance and prejudice to intrude."

The same writer, in the first edition of his work published in 1868, remarked:

"Our rule of thumb has cost us dear already, and is probably destined to cost us dearer still. It is only by putting an unfair and extravagant strain on the wealth

[1] The following paragraph from *The Times* of March 1, is an interesting confirmation of my arguments:—

THE AMERICAN STEEL RAIL TRADE.—With reference to the recent break up of the steel rail pool in the United States, it is said that the first cost to American makers of such rails is at present $15 per ton, but that probably the Carnegie Company's latest improvements in labour-saving machinery will enable it to produce them at something like $12 per ton. All steelworks are said to be making a great effort to conquer the European, and especially the South American markets, which latter had heretofore been almost monopolised by England. . . . With the help of these facilities Messrs. Carnegie and Rockefeller believe they will be able to control all markets, and to beat English railmakers on their own ground.

and energy of the country that we have managed to hide from ourselves the inconvenience we suffer, even in the lines where we think ourselves most successful, from our want of systematic instruction and science."

True at the time, these words are now doubly true. In the interval we have absolutely wasted the opportunity that was ours of securing the more important share of the coal-tar colour industry, which must be regarded as the most far-reaching of all the industries established in the Victorian era, as it carries in its train the production of synthetic products generally. Ours by right of first inception, ours as being by far the largest producers of the raw material—it has slipped away from us through sheer disregard of elementary first principles of defence, and insular narrowness of purview. Had we but appreciated and properly encouraged Hofmann and his school, how different the result might—nay, must—have been. Instead, however, of providing him with means adequate to his talents, we allowed him to languish for years in a poor one-storied building in Oxford-street, and only when too late began to think of treating him as he deserved. No foreign Government would have ever permitted such a man to be tempted away from its service. Although he returned to his native country only on a three years' visit, with the option of resuming his professorship here, on leaving our cold irresponsive atmosphere and finding himself in the warm glow of scientific enthusiasm of his fatherland, in presence of a Court at which science was deeply respected and at home, a nature such as his could not but feel the difference and elect to remain. Seeing and seizing his opportunity, he not only created a great school in Berlin, but also organised chemical science throughout Germany by the share he took in the establishment, in 1868, of the German Chemical Society, of which he remained the active leader until his death in 1892. Had he returned to us, *we* should have had a great chemical school, as the present Royal College of Science was built to plans drawn under his advice, and it was intended to devote the whole of the building to chemistry; but competition set in over the bones he had left, and they were divided without satisfying any one. We can never repair the evil wrought in those days. And all this was done under Government! Board of Trade statistics take no account of these little details, and the figures are in no way weighted thereby.

A grievous mistake was made also by the pioneers of the new industry—a mistake which was slavishly copied throughout the country, and continues to be down to the present time. It was not realised here, when laboratories were converted into manufactories, that manufactories must be conducted as laboratories if they were to remain virile institutions—that researches had to be carried on, both in order to improve the processes in use, and to discover new products to satisfy an ever-expanding public demand; no proper scientific staff was provided; and that English bugbear, the practical man without a vestige of theory in his composition, was allowed to become master of the field. Consequently, strangers stepped in who were more alive than ourselves to the necessity of working scientifically, and new prizes were instituted which they carried off: we being left in proud possession of a very honourable historical shield, but one which had become so battered that it retained little decorative value.

What does it matter—we can get our colours cheaply enough from abroad, say many; let the Germans cut each others throats, if they are so minded, in the competition to supply us at prices which, in very many cases, cannot be remunerative to them. And after all, it is worth but a few millions. But these good people forget that the loss of the colour industry implies inability to conduct any industry requiring the application of scientific skill, if it be one which must either develop or decay: and in these days there are few close boroughs in industry—secret processes are impossible. Moreover, where is the argument to stop? We may congratulate ourselves that although we eat mostly foreign bread and butter and cheese, we yet drink English milk; but we must not forget that in the future sterilised milk may perhaps be conveyed to us in tank vessels as petroleum is from America. In fact there will be no limit to the distance over which perishable articles of diet may be carried, unless our public analysts intervene more effectively in checking the introduction of preservatives such as boric acid and formic aldehyde into food materials—a modern fashion whereby, it can scarcely be doubted, the foundation is being laid in a most insidious manner for universal dyspepsia.

In short, the application of science to industry has orought the whole world into competition, and only those who fully understand and can apply all the rules and every detail of the game can hope to succeed in it. It remains to consider why we play the game so badly in many respects, and how we may learn to play it properly.

COMPRESSED AIR ILLNESS.

Compressed Air Illness; or, so-called Caisson Disease. By E. Hugh Snell, M.D., B.Sc. (Lond.). Pp. viii+251. 6 Figs. (London: H. K. Lewis, 1896.)

DR. SNELL, the London County Council medical officer to the Blackwall Tunnel, has had ample clinical opportunity of observing the results of working for various periods of time in compressed air. The book before us must be regarded as a literary *résumé* of what is known upon this subject, to which is added Dr. Snell's own experience.

Chapter i. contains an historic account of ca sson disease. The interest of this chapter is not purely medical; it will have to the general reader a distinct value as an account of the progress made in the application of compressed air for the purpose of building the foundations of bridges, and in subaqueous tunnelling. In this connection the references to the reports of the engineers, &c., are of special value. Chapters ii. and iii. relate exclusively to the Blackwall Tunnel, a short description of the engineering works being followed by clinical abstracts of fifty out of the two hundred cases of compressed air disease which came under the author's own observation. In the chapter which treats of ætiology, Dr. Snell discusses the relative potency of the

different factors at work in the causation of compressed air illness. He inclines to the view that too much importance has hitherto been attached to the length of the "locking-out" process. Other observers have laid great stress upon the necessity of the workers passing gradually from the compressed to the ordinary atmosphere, and have always advised employers to make arrangements accordingly. A factor of great importance, according to the author, is the ventilation of the compressed air space in which the men work. Tables are given, from which it appears that an increase from 4000 to 12,000 cubic feet in the supply of fresh air per man per hour was followed by a reduction, in the cases of illness per 100 days, of from 28 to *nil*. The length of stay in the compressed air, and the height of the pressure, especially the former, are factors the importance of which is confirmed by the author. At the conclusion of a criticism of the theories hitherto advanced to explain the symptoms occurring in compressed air illness, Dr. Snell, relying chiefly upon the experimental results of Bert, suggests that the symptoms are due to an escape from the blood, under ordinary atmospheric pressure, o the excess of gases which were dissolved in it, *viâ* the pulmonary capillaries, during the stay in the compressed air. The different constituents of the compressed air atmosphere have different coefficients of absorption, carbon dioxide, for instance, being eighty-eight times as soluble as nitrogen, and forty-five times as soluble as oxygen. The value of ventilation—*i.e.* frequent removal of carbon dioxide—as a preventive of compressed air illness is, according to Dr. Snell, due to its great solubility, a relatively large quantity of this gas entering into solution in the blood, in a given time, as compared with oxygen and nitrogen; hence a larger escape of gas takes place, upon reaching the normal atmosphere, when the atmosphere of the compressed air space has been rich in carbon dioxide. Thus it is owing not to its chemical, but to its physical properties, that carbon dioxide acts injuriously in this instance. Under the head of treatment the author discusses prevention and cure, the most important remedial agent being recompression. The medical air lock, used at the Blackwall Tunnel, is described. A comprehensive bibliography and an accurate index conclude the work. F. W. T.

THE ZOOLOGICAL RECORD.

The Zoological Record. Vol. xxxii. Being records of zoological literature relating chiefly to the year 1895. By many authors. Edited (for the Zoological Society of London) by D. Sharp, M.A., F.R.S., F.Z.S., &c. 8vo. Pp. 1180. (London: Gurney and Jackson, 1896.)

THE thirty-second volume of the *Zoological Record*, containing an account of the oological literature of 1895, was issued shortly before the close of last year, with its customary and most praiseworthy regularity. It is edited for the Zoological Society of London, whose property the *Record* is, and at whose expense it is carried on, by Dr. David Sharp, F.R.S., the Curator in Zoology of the Cambridge University Museum, with the assistance of fourteen other naturalists in different departments of the subject. The volume is rather thicker than those which have preceded it. In the first place, as the editor apologetically explains, this is in consequence of the literature of two years, in the case of four out of the eighteen departments left in arrear last year, being included in the present volume. But the amount of zoological work performed every year also increases as science progresses. More volumes and more papers are published, and new scientific periodicals are continually being started. All these contribute to the annual increase in size of the *Zoological Record*. To form an idea of the number of periodicals which the much harassed recorder has now to consult, it is only necessary to cast one's eye over the alphabetical list of the abbreviations of their titles, which the general editor has prepared and printed in the present volume. Each of these abbreviations is accompanied by the full title of the periodical, the place of its publication, and the most accessible libraries in London and Cambridge in which a copy of it is to be found. This list occupies fifty-four closely printed pages in the present volume, and numerous additions are made to it every year.

As regards the eighteen different reports referring to the various departments of the animal kingdom, which are included in the present *Record*, it is difficult to compare one with another—at any rate, for one who does not profess to be intimately acquainted with all the eighteen subjects. There can be no doubt that *Record* xiii. on the Insecta, which is undertaken by Dr. Sharp himself, is the bulkiest. It contains no less than 387 closely-printed pages, and the task of preparing it must have involved much time and very serious labour. But if we had to give a prize for the best of the eighteen records (putting Insecta on one side), we should rather be inclined to bestow such a reward on Mr. Lydekker, because we think his introduction is the best. Mr. Lydekker's introduction gives a short summary of the principal events in the history of mammals during the year 1895. Other recorders also give introductions, but not, we think, in so complete a form. Dr. Sharp gives us no introduction to "Aves," and Mr. Boulenger omits this very essential feature in his two records. Other authors give a few lines only, which are hardly sufficient, but many of them, we regret to see, omit it altogether. We are strongly of opinion that a summary account of the most remarkable zoological publications and discoveries of the year should be prefaced to the list of publications in every subject and recommend the general editor to insist on this being done in the future. Many naturalists are sufficiently interested in a particular subject to read such a summary, but do not care to go into the mass of details. Dr. Sharp himself sets his recorders a good example in this respect.

At the close of the volume will be found a most useful alphabetical list of the names of new genera and subgenera in zoology established in 1895, and mentioned in the present volume. The total number of such names in this volume is 1906. Last year the total number was 1438; but, allowing for the four records omitted in the last volume, and duplicated on the present occasion, the number of new generic terms would stand 1639 for 1894, and 1707 for 1895, showing, as is usual, a gradual but steady increase.

OUR BOOK SHELF.

The Story of the Weather. By George F. Chambers, F.R.A.S. Pp. 4 + 232. (London: George Newnes, Ltd., 1897.)

In a few words of preface, the author pretty distinctly indicates the object with which this little book is written. The construction, which we put upon a short imaginary conversation there given, is, that the object is as much to sell a book as to teach meteorology. But in the author's own words, the object is "to present in a handy form, and in an unconventional style of language, a certain number of elementary facts, ideas, and suggestions, which ordinary people, laying no claim to scientific attainments generally, are usually glad to know." If the author has gauged the aim of ordinary people correctly, it would seem that they are "glad to know" a quantity of miscellaneous information that some people are glad to forget. This remark applies more particularly to a stock of old world weather signs, which are introduced, not as curiosities of weather lore, but are gravely given as a trustworthy means of foretelling the coming weather. Apparently with satisfaction, and as a justification for mentioning the habits of animals as affording true weather indications, the author quotes Mr. Inwards to the effect, that these creatures seem to have been fitted with what is to us an unknown sense, informing them of minute changes in the weather. We suppose it is this additional sense which instructs a mole, when a severe winter is approaching, to be more industrious in storing up worms and food than at other times. The moon is not allowed to have any effect on the weather, or to be useful as a weather indicator, perhaps with the exception of the Easter full moon, which, on the authority of Lord Grimthorpe, has some connection with cold weather. The stars, however, do fulfil a useful purpose in indicating the character of approaching weather, and the few rules given are, it is to be presumed, among those which ordinary mortals are "glad to know."

We believe that the book would be greatly improved by the omission of all these so-called weather facts and predictions. The earlier part of the book is unobjectionable. It gives, generally, a description of meteorological instruments, a brief history of the plan and method followed in making storm and weather predictions, and just such a sketch of elementary meteorology as one would expect to find within a moderate compass.

Applied Bacteriology: an Introductory Handbook for the use of Students, Medical Officers of Health, Analysts, and others. By T. H. Permain and C. G. Moore, M.A. (University Series.) Pp. xiii + 360, and plates. (London: Baillière, Tindall, and Cox, 1897.)

"This work," so the authors write in their preface, "is intended to be an introductory handbook for the use of students, medical men, and others who require a practical acquaintance with bacteriology without having at command the necessary time for a comprehensive study of the mass of work which it comprises." After a careful perusal we must confess that the teacher, who is both theoretically and practically acquainted with the bacteriology of disease and hygiene, would hesitate to recommend this work to students and medical men, however useful it may prove to those described as the "others." The introduction, which treats of bacteria in general, is fairly sound, so far as it goes; but it is somewhat superficial, and adapted rather to the requirements of the Extension Student or County Council Lecturer than to those of the serious inquirer. Chapters ii. and iii. deal with the apparatus and methods used in bacteriological work, and just as well might have been omitted, because, as we have pointed out on previous occasions, the *technique* can be learnt only in the laboratory, and "those who have little or no previous knowledge of the subject," that is those for whom, according to the authors, this work has been written, could not possibly acquire a knowledge of methods from the meagre and not always lucid instructions given. The ætiology of infective lesions and the problems of immunity are discussed in a manner which shows an almost total disregard of the principles underlying preventive medicine, undoubtedly the most important branch of applied bacteriology. Until we come to the chapter on fermentation it is always the same unsatisfactory reading: superficial and often careless reasoning, incorrect statements, dogmatic deductions which are irritating in the extreme to those acquainted with medicine. One of the worst chapters is that on the typhoid bacillus; it is misleading and full of errors of judgment and of fact; the chapter on cholera is not much better, and, in fact, little can be said in praise of any section dealing with disease. Names are also frequently misquoted: thus we read of Grüber instead of Gruber, Corbett instead of Cobbett, and Prof. Marshall Ward is accused of having swallowed pure cultures of Koch's comma bacillus. The chapters on fermentation and on the examination of water and filters are the least faulty, but they also treat their respective subjects in a superficial and more or less off-hand manner. The bacterial chemistry, if considered at all, should be discussed fully and critically, and such an error as "deriving the ptomaines from the base pyridine" is almost unpardonable. The source of the coloured plates at the end of the book, which are all taken from the Atlas recently published by Lehmann and Neumann, is not acknowledged. The work cannot be recommended to students and medical men, because the authors have not fully appreciated the serious importance of their subject, and although their own reading, judged by the references supplied, appears to be considerable, they are not sufficiently familiar with medicine, physiology, and pathology to advise those who possess some knowledge of these subjects. A. A. Kanthack.

Ostwald's Klassiker der exakten Wissenschaften, Nos. 80–85. (Leipzig: Wilhelm Engelmann, 1896.)

No more serviceable or comprehensive series of reprints of scientific classics could be desired than the one to which the six volumes before us have just been added. No. 80 contains Helmholtz's paper, published in 1860, on the "Theorie der Luftswingungen in Röhren mit offenen Enden." The mathematical theory of the vibrations of the air in organ-pipes, or tubes with open ends, is well developed in this paper, and Prof. A. Wangerin, the editor of the volume, adds to it nearly fifty pages of notes on difficult points. No. 81—"Experimental-Untersuchungen über Electricität"—is a translation into German, of Faraday's paper on his electrical researches, from the *Philosophical Transactions* for 1832. It is edited by Dr. A. J. von Oettingen, who adds also a short biographical notice of Faraday. The same editor is responsible for the two succeeding volumes, Nos. 82 and 83, which contain Steiner's masterly contributions to geometry, under the title of "Systematische Entwicklung der Abhängigkeit geometrischer Gestalten von einander." In this work, Steiner reviewed the propositions of other geometers on porisms, projection-methods, transversals, duality and reciprocity, &c.

Nos. 84 and 85 of the series contain Caspar Friedrich Wolff's "Theoria Generationis," published in 1759. Both volumes have been translated into German, and edited, by Dr. Paul Samassa. In the first of the two volumes is the general explanation of the plan of Wolff's theory of organic development, and the section on the development of plants; the second part deals with the development of animals, and general conclusions.

Inorganic Chemical Preparations. By F. H. Thorp. Pp. 238. (Boston, Mass.: Ginn and Co., 1896.)

THIS work is divided into two parts, the first being an introductory chapter on general chemical operations such as solution, precipitation and filtration, and the second containing detailed directions for the preparation of 100 inorganic salts. The instructions in the first paper are very minute, and are apparently intended for elementary students. In the second part the arrangement followed is alphabetical, and it is stated in the preface that no attempt has been made to observe any particular grouping or sequence in the preparations. Thus the first preparation described is that of anhydrous aluminium chloride, and this is followed by aluminium hydrate and sulphate, preparations of quite another order of difficulty. This lack of arrangement and want of gradation seriously detract from the value of the book for teaching purposes. Little or no stress is laid upon the purity of the product, although the removal of one impurity is occasionally given, such as copper in the preparation of lead acetate. The preparation of pure iodine or silver, or even of pure water, according to the methods of Stas, would possibly be of higher educational value, and certainly be more interesting to the student than the formation, say, of barium and lead chromates by precipitation. A few of the equations given for the reactions require some revision. Thus for aluminium chloride we find

$$Al + Cl_2 = AlCl_3,$$

but for phosphorus trichloride

$$P + 3Cl = PCl_3.$$

As a collection of recipes, the work will be handy for reference in the laboratory. The inclusion of the methods of preparing some common reducing agents, such as cuprous chloride, chromous chloride, and sodium hyposulphite, would have added to the value of the book.

The Practical Photographer. Edited by Matthew Surface. Vol. vii. Pp. 332. (Bradford and London: Percy Lund, Humphries, and Co., Ltd., 1896.)

THIS very attractive volume should be seen by all who are interested in photography. The illustrations in it are striking examples of what can be done in the way of reproducing illustrations by photographic processes. Of especial interest is the series of short articles on photography and photographers in Japan. The aim of the editor seems to be to show the best that photography is capable of, whether in art or science or commercial application, and he may be congratulated upon the successful way in which he carries out this programme.

Life Assurance Explained. By William Schooling, F.R.A.S. Pp. xvi + 185. (London: Cassell and Co., Ltd., 1897.)

THE principles upon which life assurance is based are stated very clearly in this book, and without reference to the merits or otherwise of individual companies. The book presents some instructive points for elementary students of vital statistics and actuarial methods. It is also a practical and a trustworthy guide, which should be consulted by every one who contemplates taking out an insurance policy of any kind.

Wasted Records of Disease. By Charles E. Paget. Pp. viii + 92. (London: Edward Arnold, 1897.)

IN the three chapters of this book Mr. Paget reviews the attempts made to secure or establish permanent systems of disease registration; legislative recognition of the need for such registration, and its shortcomings; and steps advisable to secure a permanent and useful system of national disease registration. His plea for the establishment of a national system of notification and registration of disease, will have the support of most practitioners and officers of public health.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Specific Characters.

DR. A. R. WALLACE, in his extremely interesting paper on "The Problem of Utility," lately published in *Linn. Soc. Journ.—Zool.*, vol. xxv., arrives at the conclusion (p. 486) that "every species (of the higher animals at all events) will usually possess at least three peculiarities: in the first place, it must exhibit some difference of structure or function adapting it to new conditions; secondly, some distinction of colour, form, or peculiar ornament serving as distinctive recognition-marks; and, thirdly, the physiological peculiarity of some amount of infertility when crossed with allied species. The first two constitute its 'specific characters.'"

Now it appears that the first of these differences is the fundamental one, and we ought not to find species living under exactly the same conditions and in precisely the same manner, separated only by infertility or "recognition-marks." Yet any one examining the current literature of entomology, would suppose that in numerous instances there were no differences whatever between allied species than those either of the class of "recognition-marks," or in the structure of the genital organs. That this would be an extremely erroneous supposition I am convinced both by experience and on theoretical grounds, and I would ask entomologists to produce even a single valid instance in support of it. The fact is, that the specific characters of the first class are overlooked by those who describe insects, until the describers come to imagine they have no existence. Nor is this surprising, since they are largely such as can only be elucidated by observations on the living insects, and no amount of cabinet-study will detect some of them.

It follows from the above considerations that species may occur which are perfectly distinct, but nevertheless offer no palpable differences in dead specimens. I know several instances of this sort, they are what I have termed *physiological species*. As Dr. Wallace states, recognition-marks are practically universal among the higher animals, but there occur groups in which they could not be of much, if any, use; and here it is that the separation of the species becomes so intricate. It is fortunate that many groups in which recognition-marks are reduced to a minimum, the organisms are minute and often transparent, so that their whole structure can be seen under the microscope.

In the case of insects, physiological species appear among the degraded forms, such as the Coccidæ and the bird-lice. Thus the coccid *Aspidiotus aurantii* is a great pest of orange-trees in California, the Eastern Mediterranean region, &c., but in Jamaica occurs a form of it, not distinguishable structurally from the type, which never attacks the orange. Lately Prof. Kellogg, in a paper on bird-lice, stated that a certain so-called species had a great number of hosts, and probably consisted of several species, confined to particular genera or species of birds; but, nevertheless, all attempts to separate them on structural grounds had proved unsatisfactory and inconclusive. Both the coccids and the bird-lice are creatures in which recognition-marks could not be of much service. The males of many Coccidæ, which are never seen by the females, are remarkably uniform in appearance, considering the structural diversities of many of their mates, the latter having contrivances for protection against parasites, against too rapid evaporation or too great heat, for the protection of the eggs, for concealment, and so forth. In *Orthezia*, which has a tolerably active female, the male has a beautiful caudal brush. Among plants the same sort of thing occurs. The higher plants exhibit diverse flowers for recognition by insects; but how subtle are the specific characters of many bacteria, fungi, and even ferns and grasses! Yet the species are distinct, as we see, for example, in the obviously different diseases produced sometimes by bacteria which are hardly or not distinguishable. Thus Dr. Kanthack tells us (NATURE, vol. lv. p. 211): "No one nowadays ventures to define the cholera germ; there are two many varieties of it . . . We have come to the conclusion that when a bacillus is morphologically identical in appearance with the diphtheria bacillus, and in its biological characters closely resembles the conventional

type of the diphtheria bacillus, he must be a bold man who ventures to say off-hand that this bacillus is or is not a diphtheria bacillus." Yet the same difficulty does not exist in diagnosing cholera or diphtheria.

I do not suppose that recognition-marks are wanting in many groups of higher animals, even higher invertebrates. The fresh-water bivalves can hardly be supposed to present them, and hence their separation into species becomes exceedingly difficult. But it appears that recognition-marks need not be in colour or markings, but may be, and often are, in odour or voice, which are not observable in dead specimens. Thus the nocturnal lepidoptera, the species of which are often perplexingly similar, undoubtedly many of them emit subtle odours—too subtle usually for us to appreciate. So also, some species of birds are known, which are almost exactly alike in the preserved skins, but are readily distinguished in life by the song or voice.

T. D. A. COCKERELL.

Mesilla, New Mexico, U.S.A., February 7.

The Force of a Ton.

Your readers will notice that Prof. Greenhill (p. 365) uses symbols as mere numbers, and that, so long as he does this, it can be of no possible interest or importance whether he writes *m* pounds or *w* pounds, or *n* or *a* or *b* or *z* pounds.

If he intends anything definite by his hint that "Dr. Lodge can testify to the treacherousness of *g*," will he kindly give a reference? Perhaps he is thinking of NATURE, 1891, vol. xliii. p. 513.

It is a little surprising that the label "5000 tons-weight" on a hydraulic press capable of exerting that thrust, should be considered liable to mislead a practical man into supposing that the piece of metal itself was so extremely heavy; but, though the addition of the syllable "weight" in that connection would have been both cumbersome and needless, and I should never have thought of suggesting it, I cannot see that it makes the slightest difference to his argument either way. Nor, I am almost glad to say, do I appreciate any of his other difficulties; especially not the difficulty said to be caused by "tossing standard weights in the air!" It reads like the popular method of studying geology "upon the Stanislaw." *Why* do they then weigh more? Is it because they come down with a bang?

Prof. Greenhill is very persistent about this question of a force-unit; but his justification lies in the fact that he is really tilting against the whole idea of *absolute measure*—that truly practical and most useful conception which this century owes to Gauss and Weber and to Thomson and Tait. All new ideas must pass through their era of attack, and should emerge the better for the process. The idea of absolute measure is still not finally and restfully settled down in the minds of all physicists; it is still too much mixed up with the comparatively trivial question of the particular kind of unit that shall be most commonly employed for numerical specification. Prof. Greenhill is doing indirect service to the better method by his resolute insistence on conservative traditions.

I rather regret Prof. Fitzgerald's letter (p. 389), because, although containing many statements which are manifestly true, it tends to confuse the issues.

Does he really maintain that the English words mass and massive should never be used in an accurate physical sense? Is he prepared to object to the expressions "quantity of heat" and "quantity of electricity" as well as to "quantity of matter"; or does he think that whereas those other quantities may be measured in various recognised ways, the quantity called "matter" cannot be legitimately measured by any of its inalienable properties? Does he hold that the conservation of matter, as ascertained by the constancy of its inertia and of its weight under various conditions, is a wholly metaphysical and confusing idea?

How would he wish us to express the gravitational attraction between two masses, $\gamma mm'/r^2$; the *m*'s do not stand for inertia there? The physical factor *g*, which turns mass into weight without necessarily altering the numerical specification in any way, may be regarded as an abbreviation for $\gamma E/R^2$, with a correction for the shape of the earth and an allowance for centrifugal force, and is not a thing to be lightly ignored or introduced for the sake of some entirely imaginary convenience about units; not even for the sake of complicating mechanics, after all these years, by trying to express mass in something else than mere grammes or pounds or tons. Let the British student say so many pounds when he interprets *m*, and let him say so many *pounds-weight* when he interprets *mg*, and there is no difficulty whatever.

Lastly, does Prof. Fitzgerald seriously propose to introduce a new and impractical inertia unit, based upon the intensity of gravity near London, for general scientific purposes, or only for engineering-students' consumption; and, if the latter, does he hope thereby to heal the supposed breach between science and practice?

O. J. L.

Immunity from Snake-Bite.

THAT a relative immunity is acquired after a certain number of bee stings, as mentioned by Mr. R. C. T. Evans (NATURE, February 18, p. 367), is, I believe, admitted by most bee-masters. But from the few inquiries I have been able to make, the degree of immunity varies very much in different individuals, though when acquired it would seem to be permanent, or at least long-lasting.

A certain degree of immunity is acquired also by most persons against the stings of those varieties of insects which in Norway are commonly called *Myg*, and in East Anglia, to the great indignation of those who really suffer from them, Gnat. The reaction of different individuals to the stings of these mosquito-like insects is very different in degree, but on the whole the resident suffers less than a new comer. A curious fact is that in many susceptible persons there is a distinct periodicity in the phenomena which follow a sting. The immediate result is a small flattened wheal, 3 to 4 mm. in diameter, of a pale colour, but surrounded by a zone of pink injection. This is attended by itching, but both wheal and itching have gone in less than an hour. About twenty-four hours later the part begins to itch again, and in a few minutes a hard, rounded, deep-red papule, about 10 mm. in diameter, appears, and is quickly surrounded by an area of œdematous skin. The formication is intense, and in the affected area, while ordinary tactile sensations are dulled, those for temperature and painful sensations are exaggerated. In two or three hours the itching diminishes, and the œdema disappears, leaving a small red papule which itches little, if at all. After another interval of twenty-four hours, or more often rather less, all the phenomena recur, but with diminished intensity; a third, a fourth, and even a fifth recurrence usually takes place, but on each succeeding occasion the itching and swelling are less severe. After the periodic exacerbations have ceased, a small indolent papule persists for weeks, sometimes for months. This periodicity is not observed in all persons, and is certainly most marked in those who suffer most severely. In the same individual the reaction is very much greater after some bites than after others.

Whether the "mosquito" injects a toxin, or whether it is merely in some instances the carrier of a pathogenic microbe, might be worth ascertaining.

DAWSON WILLIAMS.

February 19.

Copper and Oysters.

IN my previous letter (p. 366) I had not gone into details, but Prof. Herdman's remarks on it induce me to do so.

The oysters referred to were brought to me by Mr. G. I. Wells, F.I.C., who had already examined some of them, and found copper to be present in such quantity that it could be readily dissolved out, direct from the oyster, with cold dilute nitric acid.

These observations I fully confirmed. The oysters were, no doubt, very exceptional ones, and they were believed to have caused diarrhœa in persons eating them. Most of them were free from colour, and from these no copper could be detected by direct treatment with dilute nitric acid; whilst from the coloured ones, sufficient could be obtained to easily prove the presence of that metal.

Some of the oysters were dark green, and others a bright sky-blue, the colour being in patches, and in one oyster almost entirely concentrated in the large muscle for closing the shell.

Assay Office, Chester, February 23.

W. F. LOWE.

MISS KINGSLEY'S TRAVELS IN AFRICA.[1]

THE record of Miss Kingsley's wanderings in West Africa has been deservedly praised by many reviewers. It contains most of the elements which combine to secure success for a book of travel. The land it deals with is familiar by name to all, but it is practically an unknown land; for few visit it except in an official capacity, and few of the official visitors have the inclination, or it may be the permission, to speak openly of what they have seen. Miss Kingsley has a sprightly manner and a thoroughly unconventional literary style, as beseems a lady travelling in a land so unfrequented of the tourist. The sparkle is, perhaps, too sustained to be altogether natural, and the reticence regarding her own sufferings, which must have been considerable, may perhaps lead readers to under-estimate the difficulty and dangers of her exploits. The book stands alone as a vivid picture of West African life by a writer whose point of view is as nearly impartial as we can ever hope to see. Miss Kingsley is an enthusiastic collector, but not exactly a scientific person; she is sympathetic simultaneously with the cannibal tribesman, the missionary, the trader, and the official, and in her whole book she does not say an unkind word of any one she met. As is usual with the writings of ladies who have travelled, her book is in many respects more outspoken than a man would have made it, while stopping as far short of ethnographic fulness as is necessary in a popular work. The descriptions of tropical nature on the beach and the mountain, in the swamp and the forest, are occasionally brilliant in their pictorial strength.

Yet we cannot, in a notice in a scientific journal, overlook flaws which impair the usefulness of the book if they do not impede its popularity. The journey described lay chiefly in French Congo and Cameroons—French and German possessions respectively—the topography of which is left nearly blank in most of our modern and otherwise up-to-date maps of Africa. In French and German maps, however, the river-systems, mountains, and villages are marked in abundant detail. Comparatively few English readers have a foreign map of Africa at hand to refer to, and few books so urgently demand a good large-scale map as this; yet no map is given, and there are continual references to places for which the average reader will search his atlas in vain. Perhaps a more serious fault is the humorous sparkle of the style, to which reference has already been made. Hyperbole is frequently carried too far, because only persons whose knowledge of the coast and of science in general is at least equal to Miss Kingsley's, can disentangle metaphorical from instructive statements. "Beetles the size of pie-dishes," steamers which "have a mania for bush, and the delusion that they are required to climb trees," the air being "semi-solid with the stinking exhalations from the swamps," or containing "99½ per cent. of water," and the like, are of course perfectly harmless pleasantries. But their recurrence shakes one's confidence in statements which the reader has no *à priori* means of pronouncing upon, such as the dictum regarding a large earth-worm. "He was eleven inches and three-quarters," or the gruesome observation that "dead black men go white when soaked in water." We feel strongly that those who are fortunate enough to visit regions where few can go, and who are endowed with such exceptional powers of description as Miss Kingsley, should consider the case of serious students who, when they ask for facts, do not care to be offered a cryptic joke.

FIG. 1.—Caravan for Stanley Pool, Pallaballa Mountains, Congo.

[1] "Travels in West Africa, Congo Français, Corisco and Cameroons." By Mary H. Kingsley. Pp. xvi + 744. Illustrated. (London: Macmillan and Co., Ltd., 1897.)

After all, Miss Kingsley's little jokes are lively reading, and they will afford jaded examiners many a laugh years hence, when they appear as solemn assertions taught by the intelligent teacher who "read them in a book of travels." The collection of eighteen species of reptiles and sixty-five species of fishes, brought home from the Ogowé and other rarely visited regions, form a solid contribution to science, no less than sixteen of the fishes being new. These are described in an appendix by Dr. Günther, reprinted from the *Annals and Magazine of Natural History*. Mr. W. F. Kirby also describes eight new species of insects, and catalogues a considerable number.

The narrative touches lightly on the voyage out, gives lively notes of the condition of nature and man in Sierra Leone, the Gold Coast, Lagos and Fernando Po, and then proceeds to give a detailed account of two expeditions which are perhaps the most remarkable ever made by a white woman in equatorial Africa. The first of these includes a description of French Congo, a voyage up the Ogowé in river-steamer and canoe to the borders of Ashongo-land, made famous thirty-five years ago by Paul du Chaillu, where Miss Kingsley was fortunate enough to see gorillas in their natural surroundings. From the Ogowé she made a daring, in fact, considering her report, a reckless journey through the country of the cannibal Fans, accompanied only by natives, and occasionally wading swamps "up to the chin in water" until she emerged on the Gabun estuary. Next came a short but interesting visit to Corisco Island, a Spanish possession; and the last exploit recorded was the climbing of Great Cameroons Peak (13,760 feet) in the German Protectorate, a feat which Miss Kingsley says she was "the third Englishman" to accomplish. The description of the climb is full of interest.

The chapters on fetish, and the long appendix on trade and labour in West Africa are of real value, and, being more serious in their style than the narrative, details may be accepted with some confidence. The literature of fetish lore on the West Coast of Africa is already by no means inconsiderable; and Miss Kingsley applied herself diligently to the task of extending it. She acknowledges great assistance from white residents on the coast, especially from the veteran missionary, Dr. Nassau, who has lived in West Africa since 1851; but she also got much information directly from the natives.

The doctrine of the multiple soul among the Calabar negroes is very well described. These souls are four—the soul that survives death, the shadow on the path, the dream soul, and the bush soul. The bush soul is detachable from the body, but if damaged or killed on its wanderings the body suffers the same fate. Hence old people are held in respect, even if known to be wicked, because their bush souls must be particularly powerful and astute. The soul that survives death is liable to reincarnation either in a higher or lower form. The dream soul is the particular care of witches, who lay traps for it, and return it to the owner on payment. Miss Kingsley believes that common-sense underlies many even of the most revolting fetish customs; for example, the custom of killing the wives of a chief on his death is a safeguard against poison being mixed in his food while he is alive. No trace of sun-worship was detected, nor did tree-worship appear to explain many of the fetish beliefs. An instructive contrast is drawn between the beliefs and customs of the pure negroes of Upper Guinea, and the people of Bantu affinities in the Congo and Ogowé Basins.

The relation of the African native to civilising influences is fully considered. Miss Kingsley, in spite of her frank admiration of the noble characters of the missionaries she met, believes that they are working in an entirely wrong direction, and are responsible for producing many of the evils they try to cure. She considers that missionary teaching develops the emotional parts of a black man's character, which were originally in excess, and does nothing for his industrial powers, which are naturally very feeble. She approves of teaching the natives to work in plantations and at trades actually useful to them in their present style of life, rather than teaching them to read and to become printers, bookbinders, and the like. She would not interfere with polygamy or domestic slavery, both these institutions being in many ways necessary to the negro, and not necessarily retarding his progress in civilisation. With regard to the drink traffic, she shares the official view that the West Coast African is not particularly intemperate, a large part of the imported liquor being sent far into the interior as payment for trade-goods, and a certain proportion being poured away as fetish offerings. Alcohol she holds to be necessary for the preservation of health in the swamps during the rainy season, and trade-gin appeared to be far less deleterious than the native palm-wine.

NOTES

M. VIOLLE has been elected a member of the Section de Physique of the Paris Academy of Sciences, in succession to the late M. Fizeau.

PROF. W. RAMSAY has been elected a corresponding member of the Royal Academy of Bohemia, and also of the Academy of Sciences of Turin.

ON April 21, Sir Archibald Geikie will commence the course of six lectures which he has been invited to deliver at the Johns Hopkins University, Baltimore, on the principles of geology.

THE desirability of holding an International Congress of Mathematicians has been for some time past widely felt, and we are glad to announce that the project is now about to be realised. A Committee has been formed for the purpose of organising a Congress, to be held in Zürich on August 9, 10, and 11, 1897, in which mathematicians from all parts of the world are invited to participate. The Committee includes the following names:—H. Bleuler and H. Burkhardt (Zürich), L. Cremona (Rome), G. Dumas, J. Franel, and C. F. Geiser (Zürich), A. G. Greenhill (Woolwich), A. Hertzog (Zürich), G. W. Hill (West Nyack, U.S.A.), A. Hurwitz (Zürich), F. Klein (Göttingen), A. Markoff (St. Petersburg), F. Mertens (Vienna), H. Minkowski (Zürich), G. Mittag-Leffler (Stockholm), G. Oltramare (Geneva), H. Poincaré (Paris), J. Rebstein and F. Rudio (Zürich), K. Vondermühl (Basle), and F. H. Weber (Zürich). All communications or inquiries relative to the Congress are to be addressed to Prof. Geiser, Küsnacht-Zürich. It is confidently expected that a large number of mathematicians will attend the Conference.

PROF. LOEFFLER, of Greifswald, and Dr. Frosch, assistant at the Koch Institute, have, says the *British Medical Journal*, been entrusted with the inquiry into the foot and mouth disease, for which a sum of 20,000 marks (1000*l.*) has been voted by the German Government.

WE regret to have to record the following deaths:—Mr. Henry Charles Forde, a member of the Council of the Institution of Electrical Engineers, and connected for many years with the construction and laying of submarine cables; Major Charles E. Bendire, honorary curator of the Department of Oology in the U.S. National Museum; Dr. Bernhard Lundgren, Professor of Geology in the University of Lund.

IN consequence of the growing importance of carbide of calcium, and the fact that the mere contact of moisture with this

material causes a dangerous evolution of acetylene, the Home Secretary has caused inquiries to be made into the subject, with the result that an Order in Council has been made, bringing carbide of calcium within the operation of the Petroleum Act. Accordingly, from the date on which the Order comes into force—viz. April 1—only holders of a licence under the Petroleum Act may lawfully keep carbide of calcium.

WE learn from the *Lancet*, that the German Commission for the study of the plague will leave Germany for India in a few days. The members are Prof. Koch, Prof. Pfeiffer (of the Institution for Infectious Diseases), Prof. Gaffky (of Giessen), Dr. Disuderic and Dr. Sticker (of the Imperial Health Office). Prof. Koch will travel direct to Bombay on the completion of his investigations in South Africa, and till his arrival the leader of the Commission will be Prof. Gaffky, who was with Prof. Koch in British India during the great cholera epidemic of 1884, and assisted him in the researches which finally led to the discovery of the comma bacillus.

MR. POULETT WEATHERLEY, who has for some years been travelling in Central Africa, has recently explored Lake Bangweolo. We learn from the *British Central Africa Gazette* that Mr. Weatherley has completed the circumnavigation of the lake, and has taken a number of careful sextant observations. His opinion is that M. Giraud's survey of the lake is a little faulty. Mr. Weatherley visited the tree under which Livingstone's heart is buried at Old Chitambo. He remarks:—"It is a thousand pities that some attempt is not made by people at home, who are interested in Livingstone and his work in Africa, to prevent the exact spot where he died from being hopelessly lost sight of, as it will be in a very few years. When the poor old Mpundu tree falls through fire and decay—it is now fast becoming a mere shell—after having kept guard so faithfully all these years—a quarter of a century now—there is nothing to replace it. Nothing could possibly be more appropriate than the simple rugged tree standing over the spot; no monument could be more inexpressibly solemn, but, unfortunately, it cannot last for ever. The Mpundu must go, and with it, unless prompt steps are taken, goes the knowledge of the site of Livingstone's last halting-place."

IN a paper read before the Royal Botanic Society on Saturday last, Mr. William Martindale, a member of the Council, advocated the establishment by the Society, in their gardens, of an institute for the teaching of botany, which, he suggested, should be similar to the institutes on the continent. He urged that the institute would be of vast importance to colonists and emigrants, who now went to Germany in considerable numbers for instruction. He also stated that the medical and pharmaceutical schools would doubtless supply the institute with many of its students. In the discussion which followed the reading of the paper, Dr. Scott said it was an extraordinary anomaly that not one institution which taught botany in London had a botanic garden. He expressed his entire sympathy with the proposal. Prof. Oliver also spoke in favour of the proposed institution, which, he said, would be welcomed by all the botanists in London. Several other botanists expressed their appreciation of the scheme.

AN interesting lecture was recently delivered before the Sheffield Society of Engineers and Metallurgists, by Mr. Thomas Andrews, F.R.S. For some time Mr. Andrews has studied the various aspects of the loss of strength in iron and steel by reason of use. He has made exhaustive microscopical chemical and physical examination of rails of known age and condition of service on main lines of railway, and has thus obtained much valuable information on the subject. In the course of his remarks, Mr. Andrews showed the difference between the loss of strength from mechanical abrasion and the deterioration of the ultimate crystalline structure of the metal under the fatigue of stress consequent on the presence of internal micro-flaws. He also demonstrated the effect of low temperature in reducing the impact resistance of rails, the influences of corrosion, and the manner in which vibratory stress induced microscopic internal growing flaws in rails. Allusion was made to the influence of various kinds of ballast on the permanent way. The lecturer compared the structure of old rails of long service with that of modern ones, and pointed to the sources of weakness, at the same time indicating the structure best calculated to yield the most durable and safe results. Mr. Andrews expressed a hope that the labours of the Royal Commission on the loss of strength in steel rails would result in a general improvement in the quality and trustworthiness of the metal.

WE have several times called attention to Dr. G. Folgheraiter's interesting observations on the magnetisation of Etruscan vases. Hitherto there has been a slight uncertainty as to whether the magnetisation may not have undergone some modification during the many centuries that have elapsed since these vases were baked. In his latest contribution to the *Atti dei Lincei*, Dr. Folgheraiter dispels any doubts on the matter by his observations on some vases which were pieced together from scattered fragments, discovered in excavations at Arezzo. If the magnetisation of the *terra-cotta* had in any way altered since they were broken, it is clear that the different portions would have been differently affected, and the mended vases would have shown somewhat irregular magnetisation. So far from this being the case, they were found to be as regularly magnetised as those which had been excavated entire, the opposite poles at the mouth and base being exactly 180° apart. The only remaining element of uncertainty is what was the orientation of the vases in the kiln; and Dr. Folgheraiter hopes that further excavations may lead to the discovery of potteries of the Etruscan epoch containing vases *in situ*. Should he be successful, we may look forward to exact determinations of the magnetic elements, which will greatly add to our knowledge of terrestrial magnetism.

DR. JULIUS PRECHT, of Heidelberg, has just published an important thesis on the kathodic rays, Röntgen rays, and other radiations emanating from vacuum tubes; which confirms the view that these rays are of a highly complex nature. Besides the rays capable of being deflected by a magnet according to the law of Biot and Savart (which the author has verified by photography), Röntgen's, Goldstein's, and Lenard's rays are shown to be distinguishable by their chemical and photographic effects. Dr. Precht considers that a portion of the radiation from a discharge tube is not a wave-motion, because the absorption of the rays in passing through paper varies with the time of duration of the radiation: it is suggested that this portion may be electric in its nature. Interference phenomena were obtained with direct and reflected Röntgen rays, and from these their wavelength was found to range from 370×10^{-6} to 830×10^{-6} mm.; and observing that transverse light-waves of this length cannot pass through black paper, the author seems to incline to the theory of longitudinal waves. By such interference experiments, wave-lengths were obtained nearly twice and four times as great as those found by Voller in observing the diffraction produced through a slit.

WHY is it that a dietary consisting entirely of cereals and preserved meat induces the symptoms of scurvy? Dr. A. E. Wright, professor of pathology in the Army Medical School, Netley, has lately discussed the facts bearing upon this question, and he concludes that scurvy is really a condition of acid-intoxication. This theory seems to be sup-

ported by the experience of explorers and others who have had to contend with scurvy. There are only three methods which have been definitely shown to exert an influence in warding off and ameliorating the scorbutic condition. Each of these methods consists essentially in the administration of an alkaline food-stuff (blood, fresh vegetables, and lime-juice all come under this denomination). Of each of these methods it may, therefore, be asserted that it is a method which is calculated to ward off and ameliorate a condition of acid-intoxication. Though fresh vegetables and lime-juice are used as remedies for scurvy, both of them are very slow in their action, and Dr. Wright shows that much better remedial agents are alkaline salts, such as carbonate of soda or carbonate of potash. A variety of other salts are available for the purpose; for instance, either the citrate or the acetate, or the lactate, of soda and potash, or, better still, the neutral tartrate of soda and potash. Inasmuch as the remedial agents suggested by Dr. Wright are inexpensive and eminently portable, explorers and navigators should make use of them.

IN the *Annali dell' Ufficio Centrale di Meteorologia*, vol. xvii., Messrs. A. Riccò and G. Saija have discussed at considerable length the meteorology of Mount Etna Observatory, situated at a height of 9650 feet above the level of the sea, on the southern edge of the central crater. Although the observations only cover a period of five years, and are not quite continuous, the results obtained from this peculiar locality are interesting from several points of view, and illustrate the difficulties met with at such elevated stations. During the summer season the observatory is reached from Catania after a ride of about seven hours on mules, but in winter the snow will not bear the weight of the mules; when snow is falling the observers have to use a compass, as all trace of the path is obliterated. To obviate the impossibility of living at the observatory all through the winter, a self-recording meteorograph, by Richard Brothers, which under favourable circumstances acts for forty days, has been erected by the Central Office. For more than six months of the year the monthly means of the shade temperature are below the freezing point, and this low temperature is sometimes recorded in the summer season. The absolute maximum observed was 66·4°, and the minimum, 8·1°. The diminution of temperature with height is, upon an average, 1° for each 328 feet. The amount and frequency of rainfall, &c., are less than in the plain, the number of days being on an average only thirty-seven yearly, of which six are days of rain, the remainder being of snow, or sleet.

AS a preface to the *Weekly Weather Report* for the year 1895, the Meteorological Council have just issued a valuable series of mean values deduced from the observations obtained from a large number of stations. The tables show (1) the monthly and yearly results of the daily maximum and minimum temperatures for the twenty-five years 1871–95; (2) the mean rainfall for each month and for the year, for the thirty years 1866–95; and (3) the mean monthly and yearly duration of sunshine for the fifteen years 1881–95. The values are issued in continuation of those published in the preface to the *Weekly Weather Report* for 1891, and supply very useful information relating to the climatology of the British Islands for the periods in question. In the preparation of the data, the observations at the stations of the Meteorological Council have been supplemented, to some extent, by those under the control of the Royal Meteorological Society and the Scottish Meteorological Society. These tables have been supplemented by another series referring to those stations contained in the *Daily Weather Report*, and giving additional information, showing the mean values of barometric pressure for each month and for the year, during the same period, together with the absolute extremes of the daily maximum and minimum temperatures. The highest summer temperature occur mostly in July, at times reaching 90° at severa places, the maximum being 96° in London in August 1876. The lowes temperature recorded in this latter series is – 5° at Loughborough, in the Midland Counties, in February 1895. The dryest station is Spurn Head, with an annual rainfall of 20·6 inche ; in London the yearly average is 24·8 inches. The greatest amount of sunshine occurs in May ; the south-west of England is the sunniest part, on the yearly average, while London only enjoys 25 per cent. of the possible amount.

WE have received from the Geological Survey of Alabama the first part of a Report on the Valley Regions of Alabama. It deals with the geology and economic resources of the Tennessee Valley region, is illustrated by nine photographs, and contains numerous chemical analyses of ores.

THE current number of *Brain* (Part lxxvi.) contains a paper by Dr. A. D. Waller, F.R.S., upon the action of anæsthetics, sedatives, and narcotics upon isolated nerve, with forty-three illustrations showing the effect of various drugs upon nerves. Each of these interesting records is thus a trustworthy autobiographical episode related by the nerve itself.

IN a pamphlet entitled "La Pisciface Marine," published by the Institut International de Bibliographie Scientifique, Dr. Marcel Baudouin gives an account of the hatcheries for marine fishes in the United States, Canada, Floedevig (Norway) and Dunbar, and pleads for the establishment of similar institutions on the French coast.

WE have received two publications of the U.S. Department of Agriculture :—"Contributions from the U.S. National Herbarium, Vol. v. No. 1," consists of a General Report, by Mr. John B. Leiberg, on a Botanical Survey of the Cœur d'Alene Mountains in Idaho during the summer of 1895. "Bulletin No. 4" of the Division of Agrostology is devoted to a number of papers, by different writers, entitled "Studies in American Grasses."

IN Part ix. of the *Minnesota Botanical Studies* for 1896, Miss Josephine S. Tilden points out an interesting connection between the rare and little known fresh-water alga *Pilinia diluta*, found on wet rocks, and *Stigeoclonium flagelliferum*, of which it appears to be a peculiar form, dependent on vital conditions. Mr. B. Fink describes the mode of pollination of the tomato, which is effected by bees in search of pollen. Mr. F. Ramaley describes certain points in the anatomy of the stem of the Onagraceæ.

IT would be difficult to produce a better short popular account of the discovery of *Pithecanthropus erectus*, by Dr. Dubois, than is contributed to the March number of the *English Illustrated Magazine* by W. K. Marischal. The illustrations are very instructive, and the brief text will be easily understood by the general reader. Another article in the same magazine is of the Jules Verne type, and purports to give an account of communications with Mars and journeys through space in an air-ship.

TH. THORODDSEN'S detailed history of the geography of Iceland has been translated into German by Dr. August Gebhardt. The first part of the work, dealing with the geographical history up to the end of the sixteenth century, has just been published by B. G. Teubner, Leipzig, under the title "Geschichte der Isländischen Geographie." During the past sixteen years Mr. Thoroddsen has been systematically exploring Iceland, and accumulating material for his work, a review of which will be more satisfactorily given when the completed results of his bibliographical and geographical surveys are before us.

NEW editions of several scientific works have come to hand within the past few days. Mr. W. B. Tegetmeier's work on "Pheasants, their Natural History and Practical Management" (London: Horace Cox) has developed into a third enlarged

edition. The book contains a very useful account of the natural history, habits, food, and treatment of the various species of pheasants.—Prof. Strasburger's standard work, "Das Botanische Practicum" (Jena: Gustav Fischer), is known to all botanists as an admirable book for the laboratory and the library. It first appeared in 1884, and was reviewed in NATURE shortly after publication (vol. xxx. p. 215). The original volume consisted of six hundred pages; the present edition (the third) runs into 739 pages, the increase of size being made necessary by the many additions to the knowledge of the minute structure of plants during the past twelve years. Prof. Strasburger's "Practicum" became indispensable to the botanical laboratory as soon as it appeared, and the third enlarged and revised edition of it will maintain the position gained by the first.—The fourth edition has been published of Prof. Henry Adams's "Handbook for Mechanical Engineers" (London: E. and F. N. Spon). The book is a collection of notes, definitions, and formulæ, to which ready reference is often required for examination purposes and in general practice.—Messrs. John Wiley and Son, New York, have issued a third edition of "Retaining-Walls for Earth," by Prof. Malverd A. Howe. The book includes the theory of earth-pressure as developed from the ellipse of stress, and a short treatise on foundations, illustrated with examples from practice.—Mr. Edward Stanford has published new editions of three little books by Mr. W. Thynne Lynn. The books are "Celestial Motions" (ninth edition), "Remarkable Comets" (fifth edition), and "Remarkable Eclipses" (second edition). They are so readable and accurate that they thoroughly deserve to be successful.

THE concluding part of a most valuable collection of physical tables has just been issued by the Smithsonian Institution. The work has grown out of a series of meteorological tables compiled by Dr. Arnold Guyot, and first published in 1852. These tables proved so serviceable, and there was such a large demand for them, that when the question of revision for a fifth edition arose, Prof. Langley decided to have an entirely new publication prepared. The first part of the new series (the Meteorological Tables) appeared in 1893; the second volume (the Geographical Tables) was published in 1894; and now we have the Physical Tables, to complete the work, which forms the concluding part of vol. xxxv. of the Smithsonian Miscellaneous Collections. The present volume of tables has been prepared by Prof. Thomas Gray, of the Rose Polytechnic Institute, Terre Haute, Indiana. There are altogether 315 tables of data, referring to all branches of physical inquiry. The tables are well arranged; they have also been carefully selected from the works of well-known investigators, and, as a result, they are easy of reference and can be trusted. One of the many excellent points presented by them is that the authorities from which the physical data have been derived are quoted as foot-notes to the tables. It is thus easy to find the paper or memoir from which the results are taken. A few mathematical tables are included, but only those which are useful to physicists, and which are not easily found elsewhere. Physical chemists may confidently go to the volume for data needed by them, and every one engaged in electrical research will prove the value of Prof. Gray's work. The volume is, indeed, full of facts which investigators often have to spend hours in finding; it is a compendium which no physical laboratory where serious work is done can dispense with. Physicists will be grateful to Prof. Gray for so carefully compiling these tables, and to the Smithsonian Institution for publishing them. The brief introduction on units of measurement and conversion factors will be of assistance to students using the tables.

AN experimental study of an interesting case of chemical equilibrium is contributed by M. Pélabon to the *Comptes rendus* of the Paris Academy of Sciences (February 15). When hydrogen and selenium are heated together for some time, hydrogen selenide is formed; a state of equilibrium being finally reached in which the proportions of hydrogen, selenium, and hydrogen selenide are unchanged by further heating. Similarly, if pure hydrogen selenide is heated, a mixture is finally produced containing the same three substances in equilibrium. It has been previously shown by M. Ditte, that for temperatures above 320° C. the same final system is reached, whether the initial system consist of hydrogen selenide or of a mixture of hydrogen and selenium. At temperatures below 320° C., however, M. Pélabon shows that this is not the case, two distinct curves being obtained, according as the compound of the mixture is used as the starting-point. These curves are those called by M. Duhem ("Traité élémentaire de Mécanique chimique") curves of "false equilibrium," and the hypothesis proposed by him for such systems, especially that part predicting the gradual coincidence of the curves with rise of temperature, is well borne out by the experiments of M. Pélabon.

A CONTRIBUTION to the fascinating problem of the direct production of electrical energy by the combination of carbon and oxygen, is made by Messrs. Liebenow and Strasser in the *Zeitschrift für Elektrochemie* for February 20. They have investigated the so-called Jacques cell, which consists essentially of rods of carbon and iron immersed in fused caustic alkali (see NATURE, vol. liv. pp. 298, 353.) The electrical behaviour of several metals towards fused caustic alkali was first studied. A normal electrode of mercury, covered with calomel, in contact with a solution of potassium chloride, was connected to the fused potash by means of a piece of pipe-stem moistened at one end by the potassium chloride solution, and dipping into the fused caustic potash at the other. The difference of potential between this normal electrode and an iron rod immersed in the fused alkali was then measured. For about forty minutes the potential difference remained almost constant, hydrogen being evolved from the iron, and the fused mass having a greenish colour; suddenly the colour of the melt changed to dark brown, this change being accompanied by a fall of temperature and by a large fall (about 1 volt) in the potential difference between the iron and the mercury; the dissolution of the iron also ceased. The new potential difference remains practically constant for any length of time. Similar phenomena were observed with nickel and silver. Only one value was found for the potential difference between carbon and fused alkali. The differences of potential between iron or carbon in fused caustic potash at about 500° C. and the normal mercury electrode were: active iron, −1·5 volts; passive iron, −0·38 volt; carbon, −1·32 to 1·12 volts. In accordance with these numbers, it is found that a cell consisting of carbon and iron dipping into fused caustic potash, has at first a very small negative electromotive force which rises suddenly, when the iron assumes the passive condition to about + 1 volt. The cell develops a very inconstant current, the iron being very rapidly polarised. This may be remedied to some extent by passing a current of air through the fused electrolyte.

AN interesting reaction of magnesium nitride is described in the current number of the *Berichte*, by E. Szarvasy. This substance readily reacts at the ordinary temperature with absolute methyl alcohol, a mixture of ammonia with trimethylamine being formed, about 40 per cent. of the nitrogen being found in the latter form. It appears that the methyl alcohol acts partly as water, and partly as a methoxy-compound, since the solid residue consists of magnesium hydroxymethylate $OH.Mg.OCH_3$, a white hygroscopic powder which is dissolved by acids with formation of a magnesium salt, methyl alcohol and water. When heated it is converted into magnesia, carbonic oxide, and hydrogen. It seems possible that this reaction may provide a convenient mode of preparation of the trialkylamines.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Mr. B. Dade; a Black-handed Spider Monkey (*Ateles geoffroyi*) from Central America, presented by Miss Radley; six Black-eared Marmosets (*Hapale penicillata*) from South-east Brazil, presented by Mr. John Russell; an Egyptian Jerboa (*Dipus ægyptius*) from Egypt, presented by the Hon. Mrs. Brett; two Blood-breasted Pigeons (*Phlogœnas luzonica*) from the Philippine Islands, two Barred Doves (*Geopelia striata*) from India, presented by Lady Edmonstone; an Upland Goose (*Chloephaga magellanica*), bred in England, presented by Mr. H. Birkbeck; a Black Wallaby (*Macropus ualabatus*, ♂) from New South Wales, presented by Mr. G. J. Manders; a Rough-scaled Lizard (*Zonurus cordylus*), two Cape Bucephalus (*Dispholidus typus*), a Hoary Snake (*Pseudaspis cana*), a Ring-hals Snake (*Sepedon hæmachates*) from South Africa, presented by Mr. J. E. Matcham: two Lataste's Frogs (*Rana latastii*) from Turin, presented by Count M. Peracci; two Himalayan Bears (*Ursus tibetanus*, jv.) from Eastern Asia, three Royal Pythons (*Python regius*) from West Africa, deposited; a Great-billed Rhea (*Rhea macrorhyncha*) from North-east Brazil, a Bauer's Broadtail (*Platycercus zonarius*), two Graceful Ground Doves (*Geopelia cuneata*), a Shielded Death Adder (*Notechis scutatus*) from Australia, two Dunlins (*Tringa alpina*), a Golden Plover (*Charadrius pluvialis*), British, purchased; a Hybrid Pheasant Antelope, ♀ (bred between *Tragelaphus gratus*, ♂, and *Tragelaphus spekii*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE ORBIT OF JUPITER'S FIFTH SATELLITE.—In the current number of the *Astronomischen Nachrichten* (No. 3403-4) Dr. Fritz Cohn gives a condensed account of an investigation he has undertaken with regard to the determination of the elements of the orbit of the fifth satellite of Jupiter. The observations used were those made by Barnard, with the 36-inch Lick refractor, from September 9, 1892; and by Herrn H. Struve, with the 30-inch refractor of the Pulkowa Observatory, from October 21, 1893. Fortunately for this investigation, the observations of Struve were very numerous at the opposition of 1894, when extraordinarily bad weather hindered Barnard from making many measures. Limiting ourselves to a simple statement of the results obtained by Dr. Cohn, we may say that the orbit of the fifth satellite lies nearly in the plane of Jupiter's equator, and is very nearly circular in form. Assuming a circular orbit, and finding the differences, observed minus calculated, he was led to the following values for the improvement of the elements, leaving out of account perturbations that arise from the sun and the other satellites, but which, in consequence of the smallness of the distance of the fifth satellite from the primary, are practically insignificant.

1893. *October* 30 9. *Greenwich M.T.*

$$du_0 = +\ 0^{\circ}\cdot107 \pm 0^{\circ}\cdot078$$
$$d(\Delta) = -\ 0^{\circ}\cdot124 \pm 0^{\circ}\cdot036$$
$$e = 0\cdot00592 \quad \pm 0\cdot00080$$
$$P_0 = 233^{\circ}\ 32' \quad \pm 6^{\circ}\ 55'$$

The elements, as deduced from the first two years' improved values, were as follows:—

1892. *November* 1. *Greenwich M.T.*

$$u = 226^{\circ}\cdot40 \quad u - U = 344^{\circ}\cdot46 \quad n = 722^{\circ}\cdot63160$$
$$e = 0\cdot00501$$
$$P = 207^{\circ}\cdot2 \quad \partial P = 911^{\circ}\cdot7$$

The daily motion, n, corresponds to a period of revolution

11h. 57m. 22·6790s. ± 0·0145s.

This daily motion thus requires only the small correction of − 0°·00140 to produce, according to Marth's ephemeris, the difference in the period of revolution of + 0·08s.

THE ELLIPTICITY OF THE DISC OF MARS.—In determining the ellipticity of a planet's disc by the more common methods, the error due to the position of the line joining the observer's eyes is liable to make an appreciable variation in the value deduced.

By the use of a small prism in front of the eyepiece this error can be entirely eliminated, as in the case, say, of a double star, the line joining the two components, or in the case of a planet its diameter (equatorial or vertical) can be placed in any direction with regard to the vertical.

Using the Repsold heliometer, Prof. W. Schur has taken advantage of both this method and the favourable recent opposition of Mars to investigate the question of the form of this planet's disc.

The mean values for the oblateness $(a - b/a)$ of the disc, where $2a$ and $2b$ are the equatorial and polar diameters respectively, as obtained from a series of observations made on December 2, 11, 16, 17, were as follows:—

1896		$2a$		$2b$		$\alpha = a - b/a$
Dec. 2	...	6″·265	...	6″·125	...	1 : 44·7
11	...	6·310	...	6·135	...	1 : 36·1
16	...	6·210	...	6·125	...	1 : 54·0
17	...	6·240	...	6·125	...	1 : 54·3

Taking the mean of these values, Prof. Schur finds for the oblateness of the disc a value of 1/47, the observations being freed as far as possible from all sources of observational error.

THE ROTATION OF VENUS.—Notwithstanding the persistence with which the planet Venus has been telescopically observed, the question of its period of rotation is still open. Schröter advocated a period of 23h. 21m., which was generally accepted until Schiaparelli, in 1890, stated that the time of rotation corresponded to that of revolution, namely, 225 days. Since that date M. Perrotin, Dr. Terby, M. Cerulli, and others have tended to strengthen Schiaparelli's work by endorsing his observations. On the other hand, Schröter was not alone; for M. Niesten, M. Trouvelot, and Mr. Brenner, have all deduced from their own observations that the period must be a short one, namely, about 24 hours. The question, therefore, being, so to speak, in the balance, Mr. Percival Lowell's communication to the current number of the *Astronomischen Nachrichten*, No. 3406, is of more than unusual interest. This observer has done so much for us in the case of the surface-markings of the planet Mars, that it seemed most probable that, turning his attention to Venus, we might have some definite results. Commencing observation on August 24, 1896, with the 24-inch refractor of his observatory, he found that the surface-markings were surprisingly distinct, but resembled lines rather than spots. "A large number of them, but by no means all, radiate like spokes from a certain centre." These lines look purely natural, and have not the artificial appearance of the Martian Canals.

From a great number of drawings made, a comparison showed that the rotation is such "as to keep the markings always in the same position with regard to the terminator." Thus Mr. Lowell's observations indicate that the rotation and orbital period of rotation must coincide, so that Schiaparelli's observations are again endorsed.

Other physical characteristics of the planet's surface, as observed at the Lowell Observatory, are as follows.

No clouds appear to temporarily obscure the surface details. The intense lustre of the disc is shared by all the markings, as if "a bright veil of some sort were drawn over the whole disc." This veil can be hardly anything but atmosphere; for measurements, as in the case of Mars, have given indications of twilight, and therefore of the presence of an atmosphere.

Further, Mr. Lowell states that there seems to be no evidence of polar caps. This observation does not well accord with those made by M. Trouvelot in 1877 and 1878. It will be remembered that this observer not only found very distinct markings which he termed the polar caps, but was able to describe some important details of a varying nature. In a former number of this journal (vol. xlvi. p. 468) it is stated that two of the most interesting features visible on the surface of Venus were the snow-caps at the extremities of the poles. These spots surpassed in brilliancy and importance all that M. Trouvelot had ever observed.

Lastly, Mr. Lowell has found that some markings become less distinct on nearing the central meridian. These changes vary considerably, and are found not to be a matter of obscuration. Since the positions of the markings had not moved relatively to the sun, the change could not have been intrinsic. Mr. Lowell suggests differences in the character of the rock or soil. The impression gained, on the whole, by Mr. Lowell, is that in the markings of Venus "we are looking down on a bare desert-like surface.'

PHOTOGRAPHIC REPRODUCTION OF COLOURS.

THE various methods for producing photographic pictures in colour were described by Sir Henry Trueman Wood at the Society of Arts on February 24, and examples of the results achieved by the different processes were exhibited. The main object of the paper was to bring before the Society M. Chassagne's promising process for the photographic reproduction of colour, but the opportunity was taken to summarise the whole question of colour-photography.

Though the *rationale* of the new process remains a mystery, there can be no question that very remarkable results are produced. Even more striking than M. Chassagne's pictures, however, are some transparencies exhibited at the same meeting by Mr. Bennetto, of Newquay, in Cornwall. For some time there have been rumours that Mr. Bennetto had obtained satisfactory photographs in colours, but the pictures had only been seen by a limited number of photographers before they were shown at the Society of Arts. His photographs are much clearer than those obtained by the Chassagne process, and look almost like water-colour sketches.

A short account of a private exhibition of some of Mr. Bennetto's results appeared in Friday's *Times*, and is here abridged. The methods, and indeed the principle, employed remain the secret of the inventor, and it is intended that they shall remain so until several more details and applications of the invention have been more fully worked out. All that is at present known is that the inventor claims to have discovered a system of colour photography by which can be transferred to a photographic negative, and thence printed on glass or paper, the exact natural colours of the object towards which the camera has been directed. He employs no pigments, his plates have not to be washed with various coloured solutions, and it is not necessary to view his pictures through any combination of tinted glasses. The colours are imprinted on the plate just as are the light and shade in an ordinary monochrome photograph, and are directly visible to the eye, without any subsidiary apparatus. It may be mentioned that Mr. Bennetto, in his earliest experiments, could get no effects with a less exposure than three minutes; now he is able to work with exposures of sixteen seconds.

In strictness, of course, it is not possible to know for certain that a particular result is produced by a particular process unless the nature of that process is also known; and from that point of view, it is perhaps allowable to regard Mr. Bennetto's pictures with some degree of philosophical suspicion. But he has been put to tests which it is difficult to suppose he could have satisfied did he not in fact do what he claims to do. He was requested to focus his apparatus on an easel. When he had done so, he was blindfolded, and on the easel was placed an impossible picture, painted in impossible colours, which he had never seen before. This he photographed and developed, still without seeing the original, with the result that the impossible colours were reproduced in the photograph obtained.

Whatever may have been the methods used, the pictures produced by them attain a high standard of excellence. One of the best specimens shown was a study of a sunrise, taken early one morning in the middle of June 1895, in which the fiery orange of the dawn and the heavy masses of cloud were admirably represented. The clouds, again, were excellent in a typical picture of Cornish seashore scenery, and the tints of the sand and rocks, and their reflections in the pools, were faithfully reproduced. In the case of a rock picture with wonderfully brilliant colouring, it was stated that, when the glass plate on which it was printed was examined under a microscope, not only could each individual mussel on the rocks in the foreground be clearly discerned, but that even the iridescent colours on their shells were plainly distinguishable. Perhaps the picture which best illustrated the capabilities of the process was one of a champagne-bottle standing on a white tablecloth, and surrounded with various fruits. Here there were three or four different whites which were all distinguishable, but which it would probably have taxed the powers of any artist to represent by painting. The gold-foil on the bottle was exactly rendered, and it was possible to tell that it was full by the gleam of the liquid. The inventor looks forward, among other things, to revolutionising by his process the illustration of books and magazines, and hopes to show in the future how to flash a picture on a screen so that a permanent copy may be left behind.

ON THE ALTERNATIONS OF GENERATIONS IN PLANT LIFE.[1]

IN his paper on apospory and allied phenomena (*Lin. Trans. Bot.*, 2nd series, vol. ii. p. 301) Prof. Bower says: "Already the observations of Pringsheim and Stahl have had their effect in demonstrating that no fixed and impenetrable barrier exists between the sporophore and the oophore." The suggestion thus made is far reaching in its consequences; if there be no such fixed and impenetrable barrier, then the distinction between the sporophore and oophore loses at least much of its value, and the anxious assignment of this or that structure to one or the other generation may prove to be labour lost; then the doctrine of the alternation of generations is in peril, and the mind is driven to think of a state of things in which a man should find no impenetrable barrier between himself and his father or his grandmother.

The doctrine of alternation of generations seems, therefore, to deserve reconsideration: and the principal object of the present paper is to endeavour to suggest to the attention of those more capable than myself of forming a conclusion, some considerations towards such a review of at least a part of the subject.

Another question to which I desire to call attention as I proceed is this: whether reproduction is the function of special organs only, or whether it is more or less clearly shown to be a power possessed by the whole organism—a question to which the labours of Weismann have given a fresh interest.

In this review I propose to confine my attention primarily to those classes of plants which produce a cormophyte. I do so, not forgetting that a wider survey of the subject might be yet more valuable. Under the term cormophyte I include the plant of the Characeæ, whether the description be perfectly accurate or not.

I do not propose to trace the life-history of every group of plants; but I have chosen for consideration groups which exhibit, I believe, types of every important variety of the schemes of life-history to be found in those parts of the vegetable kingdom to which the doctrine in question has been thought to have any application.

To prevent any possible misapprehension, let me say at once that when I use language borrowed from the doctrine in question, such as sporophore or oophytic generation, I do so, not as affirming the doctrine or the consequent fitness of the language, but in the endeavour to understand the view taken of the phenomena under discussion on the footing of that doctrine.

Characeæ.—In this group we have a sexual generation. The fertilised archegone becomes a fruit or spermocarp; this is detached from the parent organism. It gives rise to a primary root and a hypha-like prothallus, and from the prothallus a young cormophyte is developed like the parent. The succession of events may then be thus stated:—

Cormophyte producing { Archegone / Antherizoid }
↓
Spermocarp or fertilised archegone.
↓
Protonema or pro-embryo.
↓
Cormophyte.

Now here we must observe that there is one kind of generating cell only, viz. the sexual cell, and that there is no spore in the sense of an asexual cell, and that, as a consequence, there is no sporophytic generation.

On the first blush of the matter, a life-history such as this would seem to present nothing like an alternation of generations. At one time, however, Prof. Vines suggested that the pro-embryo was to be regarded as the sporophore which did not produce spores, but aposporously produced the oophore by direct vegetable growth (see Bower, 2 *Lin. Tr.*, p. 321). He has, however, since altered his opinion, and he now regards the development of the pro-embryo not as indicative of an alternation of generations (Vines on Apospory in the Characeæ, 1 *Ann. Bot.*, 177).

[1] The accompanying paper reached the hands of the editor of NATURE on 31 August of last year. Dr. Scott, in his valuable address as the President of the Botanical Section of the British Association, delivered more than a fortnight after that date, has, like myself, discussed the alternation of generations, apospory and apogamy, and the relations of mosses and ferns. These dates will account for my not referring to Dr. Scott's views; and on the whole I think it better to leave my paper as an independent contribution to these subjects, rather than to attempt to weave into its existing structure any references to the more authoritative contribution of Dr. Scott.—EDW. FRY.

But side by side with this sexual generation, there is evidence of two other modes of propagation amongst the Characeæ.

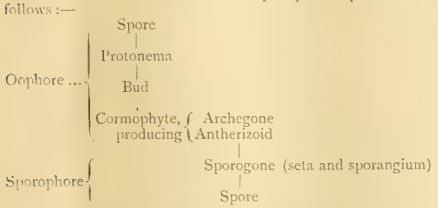
(i.) It is believed by some botanists to be established beyond doubt that in the case of *Chara crinita* in the regions of the Baltic Sea, if not elsewhere, the unfertilised archegones produce plants like fertilised ones.

(ii.) Some species of *Chara* are propagated by bulbils or agglomerations of cells, by branches known as gymnopodal shoots, or by prothalloid branches.

We are thus in the presence of facts of the last importance on the theory of reproduction. We find an organism with organs specially adapted to and formed for reproduction, and yet the same result is brought about by other parts of the plant, which seem to have no such special organisation.

And, secondly, we find that the result of these short cuts to reproduction excludes or avoids the sexual act.

Muscineæ.—Here the full life-history may be represented as follows:—



But side by side with this somewhat elaborate life-history, the mosses exhibit abbreviated modes of reproduction of varied descriptions—a multiplicity of methods of what I will venture to call, by borrowing a term from a popular branch of applied science, short-circuiting.

First we get the production of gemmæ which produce protonema like that arising from the spore, and this protonema, through the intervention of a bud, produces the cormophyte.

These gemmæ are found in a great variety of positions: in the capsules in Encamptodon (*Weissia perichætalis*), in the place of spores (Montagne, "Plantes Exotiques Nouvelles," *Ann. de Sc. Nat. Bot.*, vol. iv. pp. 119, 366): in the terminal cups which probably represent male flowers in the well-known *Tetraphis pellucida*; congregated in balls at the ends of quasi pedicels in *Aulacomnium palustre*; on the ends of the leaves in the *Orthotrichum phyllanthum* (where the fructification is very rare); in *Leptodontium gemmascens* and *Grimmia hartmanni*; on the upper half of the midrib in *Tortula papillosa*.

The next step in the abridgement of the life circle is exhibited by those cases in which protonema is produced by the cormophyte without the intervention of a gemma. "Pringsheim and Stahl found independently of one another," says Prof. Bower (*ubi sup.*), "that it is possible by cultivation under abnormal circumstances to induce a formation of protonema by direct vegetative growth from the sporogonium of certain mosses." But nature herself, apparently under no abnormal circumstances, brings about the same phenomenon. Schimper has traced the growth of protonema directly from the rhizoids in *Phascum serratum* ("Recherches sur les Mousses," p. 11), and *Polytrichum nanum* and *aloides* (p. 12); from the stems in *Dicranum undulatum* (p. 13); from the under side of the leaf in *Orthotrichum obtusifolium* (Pl. ii. fig. 6); from the mid-rib of the leaf in *Orthotrichum Lyelli* (p. 15); from the perichætal leaves in *Oncophorus glaucus* (p. 18); from the base of the leaf in *Funaria hygrometrica* (p. 19). It has been found growing from the marginal cells of the involucres of the archegone in the strange *Buxbaumia aphylla* (Goebel, on "The Simplest Form of Moss," *Ann. Bot.*, vol. vi. p. 355). Lastly, in *Conomitrium julianum* young plants often grow from the inner side of the calyptra with the intervention of a short piece of protonema (Goebel, "Outlines of Classification," Eng. Tr., p. 173).

But nature goes yet another step forward, and leaves out in some cases at once gemma and protonema; and the cormophyte produces bulbils which at once again grow into cormophytes. Thus on the rhizoids of *Barbula muralis*, *Grimmia pulvinata* and *trichophylla*, and *Trichostomum rigidulum* are formed leaf-buds, which develop into the true cormophyte (Schimper, 10-11): bulbils grow on the stem of *Bryum annotinum* (p. 14); and, lastly, we get the striking phenomenon of young cormophytes produced at the ends of the branches in *Sphagnum cuspidatum*, resembling in everything but in size the parent plant from which they are produced (Schimper, "Torfossoose," pl. 16, fig. 1). This is very striking: here nature has given the slip to spore, to gemma, to protonema, to leaf-bud: short-circuiting can go no further.

The first inquiry I suggest on the foregoing statement of facts is this: Taking the life-history of a moss in its fullest form, is it correct to say that there are two generations involved in it? And this will turn upon what we mean by a generation.

Generation.—If we regard the alternation of generations as it exists in the Medusæ and hydroid zoophytes, to which the expression, now so familiar, was, I believe, first applied by Steenstrup, it will be found that in these creatures, each generation consists of a distinct and independent organism, differing from the case of generations of men in that the one generation is produced asexually by germination, and the other sexually, and that the organisms of the two generations are different in form. The generative zooid or Medusa is detached from its stationary parent: and in like manner the young creature produced by the Medusa is detached from it before it begins to develop into the fixed hydroid colony; in the case of each new generation there is a complete solution of continuity with its parent; there is no physical connection maintained after a certain period, and there is no dependence for nutrition or any other vital process. But when we turn to the moss we find no such division into independent organisms between the oophore and the sporophore, but, on the contrary, a continued physical connection, and dependence of the seta and sporogone on the cormophyte. The two parts are organically connected. The seta and sporange are incapable of an independent existence, and are not detached from the moss plant except by death.

I suppose that a generation might, according to the ordinary understanding, be defined to be the life of an organism either independent in fact or constituted for an independent existence from the time when its whole future was gathered up into one cell to its death: but is not usually extended to include the life of a part of an organism from the time when the future of that part was gathered together into a single cell.

How are we to distinguish a new generation from the growth of a part in an existing structure? I suppose that a new generation means the origination of a new individual; that so long as there is a physical continuity in a given structure, both in fact and in design, we have the same individual; that so long as this exists, the death of a part of the structure does not convert the remaining part, or the parts which may arise from it, into a new individual; and that, in short, we never have a new generation without the solution of continuity, in fact or in design, between the old and the new. If we adopt the view above suggested of a generation, there is not in the life-history of the moss more than a single generation, and there is consequently no alternation of generations.

To extend the definition of a generation so as to include the separate development of dependent parts, would, no doubt, remind us of the fact that in the earliest stages of organisation, growth and reproduction seem hardly to be distinguished; but it seems to me to confound together two things which it is most important to separate when we are considering the course and history of reproduction.

In this connection it is convenient to consider the meaning of the words *ovum* or *ovule*. By these words I conceive that botanists mean a cell resulting from the union of two other cells of different characters, from which cell a new generation starts. The "embryo which begins the new generation is the female or germ cell (ovum, oosphere, germinal vesicle)," says Sachs. That it shall be the beginning of a new generation—of a new being, either independent or constituted for independence, is, I conceive, an essential part of the meaning of the word in question. If so, there is in mosses no ovum and no oophore: for the fertilised archegone produced in mosses is not an independent organism, but a dependent organism or part of an organism; and the really startling fact about this history of the moss appears to me to be this: that whereas in the generality of cases the fertilised ovum is itself and directly the starting-point of a new individual, in the moss the fertilised ovum produces a new growth, and that this new growth by subdivision produces a number of spores, each of which is the starting-point of a new individual. But this process in the mosses does not stand alone. It recalls the mode of reproduction in other cases. In some of the Floridæ the fertilised ovum does not directly reproduce a new

individual, but a growth takes place, and the ovum becomes differentiated into two parts—the one sterile, which forms a kind of capsule, and the other fertile, which produces numerous spores: and as in Nemalion and Batrachospermum (Bower on "Antithetic-Alternation," iv., *Ann. of Bot.*, p. 361): in others the growth after fertilisation takes place from an adjoining cell or cells of the procarp (Lejolisia, &c.); or, in other cases, from adjoining procarps to which the fertilising effect is handed on (Corallina, Dudresnaya, &c.), and this results in the formation of corpospores (Bower, *ubi supra*). Again, in the Pyrenomycetes, the result of fertilisation is the production of perithecia, or receptacles which again produce asci or sporangia, which in their turn produce spores.

These modes of generation suggest as their probable explanation one or other of two different views. The one view is that the sexual act is in these cases not reproductive, not the starting-point of a new generation—but productive only, and is the starting-point of a new organ or growth in the parent plant—so that in this view the only mode of reproduction is asexual; the other view, which appears to me the more probable, is that the fertilised protoplasm of the ovum is broken up into various parts, and that, notwithstanding the intervening stages of development, a portion of it finds its way into each so-called spore, so that the spore in all these cases is, in fact, a sexually produced cell, and the only mode of reproduction is sexual.

Perhaps some corroboration of this latter view is to be gathered from the cases in which the archegones of mosses have shown a tendency to reduplicate the growths which they produce. W. Theodor Gümbel ("Der Vorkeim—Beitrage zur Entwichlungsgeschichte der Moospflanze. Nova Acta Acad. Cæsar.," vol xxiv. part ii. pp. 578-651) has collected a number of such instances. In the *Polytrichum juniperinum* he has found an archegone producing two setæ and two capsules under one calyptra. In *Hypum pseudoplumosum* he has found two setæ grown together and bearing two capsules; in *Mnium serratum* one seta and two capsules; in *Brynn argenteum* and *Splachnum vasculosum* one seta with two capsule necks and two capsules. These abnormal growths, or some of them, may, perhaps, point to a division of the fertilised protoplasm even in the archegone; and they may be only cases of the earlier beginning of that division which normally takes place after the growth of the sporangium.

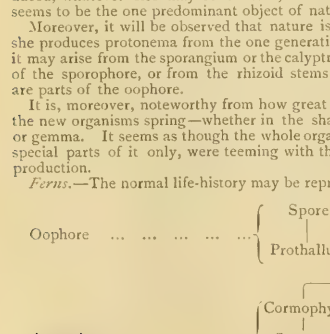
If this suggestion should be the true one, it would seem to follow that fertilisation amongst plants may produce one or other of two results: (1) it may directly result in the fertilised ovum capable of producing a new plant, or (2) it may indirectly result in the formation of a number of cells each capable of reproduction; and to this latter form of reproduction that of the mosses should be referred.

Recurring to the brief summary of the modes of reproduction in the Muscineæ, it affords room for much observation. We find apogamy in almost every form, *i.e.* we find various modes, all of which avoid and exclude the sexual union; but the economy of nature goes much beyond that, and excludes the protonema, the gemma, and the leaf-bud. The one thing which is reproduced, whatever else may be omitted, is the cormophyte; this seems to be the one predominant object of nature's care.

Moreover, it will be observed that nature is careless whether she produces protonema from the one generation or the other; it may arise from the sporangium or the calyptra, which are parts of the sporophore, or from the rhizoid stems or leaves, which are parts of the oophore.

It is, moreover, noteworthy from how great a variety of parts the new organisms spring—whether in the shape of protonema or gemma. It seems as though the whole organism, and not any special parts of it only, were teeming with the capacity for reproduction.

Ferns.—The normal life-history may be represented thus:—



So that whilst in mosses the cormophyte produces the spore; in the ferns it produces the fertilised ovum; or, to express it in the language of the theory under investigation, in the mosses the cormophyte is an oophore; in the ferns it is a sporophore.

But side by side with this normal life-history in the ferns, we have abbreviated forms to which much attention has lately been directed.

We have cases of prothallus (capable of producing the two sexual forms) arising not from the spore, but from the sporange in the *Athyrium filix fœmina*, var. *clarissima*, and in *Polystichum angulare*, var. *pulcherrimum*; we have prothallus arising from the fronds—from the apex of the pinnule or one of its segments, or from the surface of the pinnule in *Polystichum angulare*, var. *pulcherrimum*. (Prof. Bower on "Apospory," *ubi sup.*, and Druery, *Jour. Linn. Soc. Bot.*, vol. xxii. p. 437). In *Pteris aquilina* growths have been found from the sporangia "resembling in some cases moss protonemata, in others irregularly shaped prothalli" (Farlow, "Apospory in *Pteris aquilina*, 2 *Ann. Bot.*, 383).

So, too, in the genus *Trichomanes* we find similar growths of prothallus. In *Tr. pyxidiferum* it grows from the base of the sorus; in *Tr. alatum* from the tips of the pinnæ of the fronds, from the cells of the apices or margins, or from the surface of the fronds: and again in the form of flattened strap-like growths from the margins or tips of the pinnules in *Tr. alatum* (Bower, "Some Normal and Abnormal Developments of the Oophyte in Trichomanes, *Ann. Bot.*, 1, 269). *Tr. Kaulfussii* presents growths of gemmæ and outgrowths on the margins of the fronds similar to those of *Tr. alatum* (Bower on "Apospory and the Production of Gemmæ on *Tr. Kaulfussii*," S *Ann. Bot.*, 465).

We get other cases in which gemmæ are produced, and that in a variety of ways; and whereas in mosses the gemmæ sometimes give rise to prothallus and never arise from it, in the ferns they seem rather to be produced by the prothallus, and appear to produce the cormophyte by direct vegetative growth. They have been described as growing in large numbers on the margin of the thallus of *Vittaria parvula* and *Monogramme paradoxa*; and on the ends of prothalloid growths in *Tr. alatum*. They have been observed, too, on *Tr. incisum* and in certain of the Hymenophylleæ (Bower, 1 *Ann. Bot.*, 273, 283-4).

But nature goes yet two steps further in this process of short-circuiting. In *Tr. alatum* the prothallus bears flattened expansions from which grow buds, which by the ordinary course of differentiation produce the leaf-stem and roots of a young cormophyte (Bower, 1 *Ann. Bot.*, 287), and the same phenomenon has been observed in *Lastræa pseudomas*, var. *cristata* (Druery, *Jour. Linn. Soc. Bot.*, xxix. 479-481).

Lastly, as in mosses, even the prothallus stage may be squeezed out. We get a vegetative bud developed from the base of the sorus in *Athyrium filix fœmina*, var. *elegans*, or from the side of the sorus in *Aspidium* (Lastræa) *Erythrosorum*, var. *Monstrum vel proliferum* (Bower, 2 *Linn. Tr.*). The growth of such buds and small plants arising from them on the pinnæ of *Asplenium bulbiparum*, *Cystopteris bulbifera* and other ferns is a familiar sight in our garden houses.

We have thus a young cormophyte produced by direct growth from an old cormophyte—a case of the most simple and short reproduction, and I can hardly bring myself to think that reproduction without spore or ovum is justly to be regarded as the case of an alternation of generations, one arising from a sexual ovum, and the other from an asexual spore with the aid of two principles or facts—apospory, which gets rid of the spore, and apogamy, which gets rid of the ovum; such a mode of regarding a simple and direct case of vegetative reproduction seems to me to be unreal, and to savour of scholasticism. Apospory and apogamy are expressions natural enough if we adopt the doctrine of alternation of generations as one which is to be applied to all cases of reproduction in the families concerned, because without some such epicyclic doctrines the facts will not go into the theory; they are formulæ for classes of exceptions on the supposed rule; but it may be doubted whether the exceptions here are not sufficient to destroy the rule.

If we insist on the view of the two generations, we are struck by the confusion which exists between them, for the prothallus, which is part of the oophore, may arise either from the spore or from the cormophyte, and from the sorus, which are regarded as parts of the sporophore; and the prothallus itself may produce either sexual organs, and so an ovum, or it may produce a cormophyte by direct vegetative growth in the form of a gemma or a bulbil, in which case it is difficult to describe it as an oophore.

Another point which strikes the mind on the consideration of the generation of ferns as of mosses, is that the theory of an alternation of generations is applicable only to one out of many modes of generation or schemes of life, and that it fails entirely to explain the others; and that therefore, even if true, it cannot be a complete or sufficient explanation of the facts in question.

But let us for a brief space confine our attention to the full and most complex life-history of which it is suggested to be an explanation. The fertilised archegone of the prothallus of the fern does not become detached from the prothallus, but, on the contrary, establishes a closer relation with it by the formation of a sucker or foot, which communicates with the tissues of the prothallus, and draws from them nourishment for the young cormophyte in the course of its growth. When the prothallus has thus performed its functions, it withers away. There has thus never been any physical severance of continuity between the prothallus and the cormophyte, and from the first to the last moment in the life-history of the fern there has been a continuous physical relation. Now arises the question whether the death of the prothallus is like the death of a parent, or the death of part of an organism—that kind of death without which there can be no life. Is it anything more than the casting off of the leaf in autumn, or of the stipules and bracts in the spring, or of the corolla and the stamen and pistil when their part has been done, or the withering of the cotyledons? Again, I believe that I am right in holding that the prothallus has no adaptation to independent existence; that if the archegone be not fertilised, it does not long maintain its life, and that it is thus in no way fitted for an independent existence. If the view with regard to the meaning of a generation, which I have before suggested, be correct, it would seem that we have no true alternation of generations in the life-history of a fern any more than of a moss; and that, as in the mosses, the sexual union ends in the reproduction of a new individual, not directly, but indirectly only, or (according to another view) in the production of a new part of the existing organism.

A comparison of the life-histories of the mosses and of the ferns discloses, as we have seen, the remarkable fact that in the former the cormophyte is an oophore, and in the latter a sporophore, or, as stated by Hofmeister: "The leafy plant in the mosses answers, therefore, to the prothallium of the vascular cryptogams; the fruit in the mosses answers to the *fern*, in the common sense of the word, with its fronds and sporangia" ("On the Germination, &c., of the Higher Cryptogamia," *Eng. Tr.*, p. 435). If this be correct, it follows that the cormophytes of the two groups have no connection and no relation of descent, for if the fern plant were a modified moss plant, it would obviously belong to the same generation. It follows then that the leaves, the stem, and the whole vegetative structure of the mosses have no genetic connection with those of ferns or of the phanerogams. "The chasm which divides them," says Prof. Goebel (*Enc. Brit.*, s.v., *Muscineæ*, vol. xvii. p. 74), speaking of these two classes of plants, "is the widest with which we are acquainted in the whole vegetable kingdom."

On this hypothesis then it follows that the mosses are to be regarded as the highest point reached by that line of development in which the cormophyte is the oophore, or, in other words, in which the chief vegetative growth is also productive of the ovum, or sexually produced cell; and that the ferns are the first and lowest example of that line of development in which the cormophyte is the sporophore, or, in other words, in which the chief vegetative growth produces only the spore or asexual cell. The mosses, therefore, appear before us without descendants, and the ferns without ancestors.

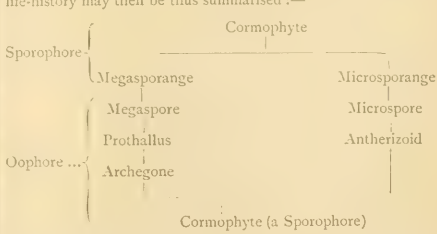
This conclusion seems improbable in itself, but it becomes more strange when we consider the fact that the Hymenophyllaceæ present themselves very much as if they were a link between the mosses and the other ferns; a view which has been long, and still is, maintained by the foremost students of these plants (Bower, "Some Normal and Abnormal Developments of the Oophytes in Trichomanes," i. *Ann. Bot.*, 269, 270). The leaves recall those of mosses, not only in their generally delicate character, but in that they often consist of only one layer of cells, and that, except in one genus, *Loxsoma*, they are without stomata. Again, as far as is known, the product of the spore of the Hymenophyllaceæ is not a prothallus, as in most ferns, but a protonema, as in the mosses. We have already seen that in many cases the protonema of the Hymenophyllaceæ acts like that of the moss, viz. that it produces a bud which produces a cormophyte: and this apogamy appears to be commoner in this group than in any other of the Filices.

If, instead of regarding the successive phenomena of the life-history of the moss and the fern as divided into two distinct generations, we regard them merely as successive events in the history of one and the same organism, and further admit the possibility of a variation in the order of these events, then we can conceive that a moss was the ancestor of the filmy fern. We shall hereafter find other cases in which it appears that the order of succession of events has been changed in allied organisms.

Perhaps this variation in the order of the events may be due to, or at least may be associated with, the different methods adopted by mosses or ferns respectively for retaining that moisture in the presence of which alone the act of fertilisation occurs. The moss is adapted to retain the dew and the rain amongst its leaves and in its perichætal growths; and the long translucent hairs, which characterise the leaves of many of the mosses which especially affect dry situations, are probably of use in retaining this moisture. Mosses are for the most part habitually damp. In the ferns, on the other hand, the presence of moisture during fertilisation is assured by an entirely different method; here we have a plate-like expansion of the prothallus, clinging closely to the damp soil and the archegones and antherizoids situate usually upon the under or damp surface. If these different classes of plants are to retain moisture at different stages of their life-history, it will seem to follow that fructification which requires this moisture must follow in the order of events this act of retaining moisture. It may be that the order of succession in the events of plant life depend, not on obedience to some inherent law or antetypal form, but on physiological necessities of life.

Rhizocarpeæ.—In this group, as is well known, we find, for the first time, the presence of two kinds of spores (so called).

The life-history is briefly this. The cormophyte (which is a sporophore) produces two kinds of sporanges—the megasporange and the microsporange. The megasporange produces megaspores, and the microsporange produces microspores. The megaspores are female and without fertilisation produce a prothallus, which bears archegones; and these archegones are fertilised by antherizoids, proceeding from the microspores. From the archegones thus fertilised, the new cormophyte is produced. The life-history may then be thus summarised:—



In the foregoing statement a difference as regards the prothallus will be observed between the megaspores and the microspores. The female prothallus is developed as a substantive growth, but in the case of the microspore this appears to be much less clear. "In Marsilea and Pilularia the antherizoids are produced in the interior of the microspores themselves." In Salvinia each microspore emits a tube which pierces the wall of the sporangium and divides into two parts, of which the terminal part is developed into antherizoids, leaving the single cell of the hinder part as the so-called prothallus (Sachs, Text-book by Bennett and Dyer, 384). It may be permitted to doubt whether that single cell can be regarded as a true prothallus; but even if it be, this is absent in Marsilea and Pilularia, so that here, on the male side, the prothallus has dropped out of the series of events.

Another point must be considered. In the case of the moss and the fern passing through the full circuit of their life-history, there are two points at which the whole future of the plant has been thought of as wrapped up in a single cell, viz. in the spore and in the fertilised archegone: in the case of the rhizocarps and all plants which follow their scheme of growth, including the phanerogams, the future of the plant is gathered into a single

cell only once in the life-history, viz. in the fertilised archegone. It seems difficult to consider in the latter case that there is more than one generation.

Can it be rightly said that in the case of the Rhizocarps there is any true spore or any true sporophore? The answer depends on the meaning which we attribute to the word spore.

Of this word many uses are made, to the confusion of thought on such subjects. It is according to the glossary to Kerner's "Natural History of Plants," as edited by Prof. Oliver, "a reproductive cell which becomes free and is capable of developing into a new individual." De Bary, in like manner, applies the term generally to "any cell which as a single cell becomes free and is capable of direct development into a new organism (Bion) without reference to its origin and homology" (cited by Bower, ii. *Linn. Tr.*, 301.) Sachs, on the contrary, would appear to confine the term to such a cell when asexually produced. "The asexual reproductive cells," he says, "usually become detached from the mother plant and dispersed (hence called spores) in order to produce a new generation at a distance from it" (Bennett and Dyer's Translation, p. 203): and in the language which contrasts oophore and sporophore, I suppose this view that the spore is asexually produced is plainly involved.

Now if we take either of these definitions and apply it to the life-history of the Rhizocarps, a curious result appears to follow. Inasmuch as the megaspore produces a prothallus of its own energy, it may fall under the description of a spore, and may be considered as the product of a sporophore and the beginning of an oophore. But neither the microspore nor the antherizoid of Marsilea and Pilularia falls under such a definition, and there seems nothing to separate it from the sporophore as a new generation, and yet the archegone of the megaspore is fertilised by it. If I follow the matter aright, the sporophoric generation on the female side has united with the oophoric on the male side for the production of the young cormophyte. If this be true, there is certainly no hard and fast line between sporophore and oophore, for the cormophyte is the one by one parent and the other by the other parent.

If the capacity to reproduce an organism like the parent be essential to the conception of a spore, then neither megaspore nor microspore is a true spore, and we have no sporophoric generation on either side.

Lycopods.—In this single group we have a most remarkable diversity of schemes of generation.

The Selaginellaceæ (as is well known) produce megaspores and microspores, and present substantially the same scheme as the Rhizocarps.

The Lycopodiaceæ, on the other hand, have a prothallus produced by a spore, and itself in turn producing archegones and antherizoids, from the union of which arises the cormophyte, which is regarded as being a sporophore. This group, therefore, presents substantially the same scheme as the Ferns.

Here, then, we have two groups of plants which botanists have agreed in regarding as closely united the one to the other, yet pursuing essentially different courses as regards reproduction. The two courses are so opposed, that whilst the sexual differentiation arises in the Lycopodiaceæ only in the oophore, in Selaginella it goes back into the sporophore; or otherwise stated, in the one this differentiation begins in the prothallus, in the other it begins before the prothallus by the differentiation of the spores into two kinds. What is the inference? Is it not this? that neither the modes of reproduction, nor the order of events in the life-history are characters of great persistency; or, in other words, that the organism is unstable in all these particulars?

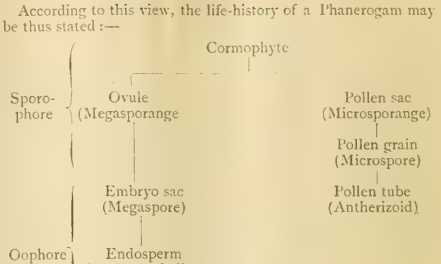
The Lycopods exhibit the phenomenon of short cuts. In *L. cernuum* it has been found that the root tops (*sic*) turn into root gemmæ or bulbs, which produce on germinating young plants much like those from the prothalli (Treub., "Some Words on the Life History of Lycopods," *Ann. Bot.*, pp. 119, 122).

Phanerogams.—The accepted application of the doctrine of the alternation of generations to this class of plants may thus be stated.

The cormophyte of the Phanerogam is, as in the Ferns, a sporophore.

The ovule	=	the megasporange.
The embryo sac	=	the megaspore.
The endosperm	=	the female prothallus.
The pollen sac	=	microsporange.
The pollen grain	=	microspore.
The pollen tube	=	antherizoid.

According to this view, the life-history of a Phanerogam may be thus stated:—



So that the dividing line between the two generations is, according to the theory in question, drawn in the same way as in the Rhizocarps, and seems open to the same observation of the mingling in pollination of two generations.

With regard to phanerogams, no fact is more familiar than that the embryo, *i.e.* the young oophore, is intimately connected with and is nurtured by the cormophyte, *i.e.* the sporophore, and thus the two so-called generations coexist in close physical union; and, furthermore, it is familiar that the fertilisation of the embryo sac (or megaspore) by the pollen tube (or antherizoid) often produces great changes in the carpels and the other parts of the perianth, and, in fact, in the whole flower-bearing axis; so that the fertilisation of the mother of a future organism is followed by great physical alterations in the structure of the grandmother.

Another familiar fact is this. In Gymnosperms the endosperm is formed long before fertilisation, whereas in the Angiosperms it is formed after that event. Now, as in the Rhizocarps so in the Phanerogams, we have only the supposed female prothallus left, for the pollen is formed without prothallus; and now, in the Angiosperms, we find the prothallus not coming into existence till after the formation of the ovule (or megasporange) and the embryo sac (or megaspore), and the fertilisation of this by the pollen (or microspore). What was regarded as a *pro* embryo is now a *post* embryo: the parent has become the child. The prothallus has, therefore, according to the theory in question, lost its old position of a growth preceding the sexual or, at least, the female organs, and does not arise til after these; it has lost its old function of producing thes organs; and, one may add, it has lost its old form, for it i no longer a prothalloid growth and no longer a substantiv organism, but is reduced to a part of the seed.

In the case of the Cryptogams, the prothallus for the mos part shows its true place in the order of events by gradually withering and dying away when the cormophyte has been started; but in the Phanerogams the endosperm is only entering on its functions when the development of the embryo begins, for it then becomes filled with nutriment, and increases in size. In a word, its duties are essentially connected with the life and growth of the embryo, so that it is functionally, as well as physically, part of the seed.

If the homology of structures so different in form, function, and order of succession, as the prothallus of Cryptogams and the endosperm of Phanerogams is to be maintained, cogent evidence ought, one would think, to be forthcoming.

The Phanerogams, no less than the other groups which we have been considering, give abundant evidence of short-circuiting. It will be enough, briefly, to refer to some instances.

The gemmæ which are found growing on the margins of the leaves of the *Malaxis paludosa* recall curiously the similar, though less complicated organised, structures in the *Tetraphis*, the *Orthotrichum*, and other mosses.

Bulbils are found in many cases on the stem in the axils of the leaves. *Ranunculus ficaria*, *Dentaria bulbifira*, *Lilium bulbiferum* are amongst the plants which present this fact.

Small young plants arise directly on the leaf in certain cases, as in *Cardamine palustris*, where the young plant arises at the bifurcation of the vascular bundles: and in many other cases they arise from the leaves upon the severance of the leaf from the plant, so that an injury to the parent leads to reproduction.

The Begonias are, as is well known, propagated from leaves to a large extent in our greenhouses; the *Hoya carnosa* and the *Aeuba japonica* exhibit the same phenomenon.

Buds are formed on the roots of trees, shrubs, and herbaceous plants, which are capable of the direct production of young plants of the same kind as the parent. Every one knows that the gardener avails himself of this familiar fact for the purpose of increasing his stock in a very large number of plants. One point only requires further mention, viz. that the tendency to produce young plants from roots is in some cases produced, and in others is greatly increased by the destruction of the parent plant. This seems to show that the same cells or parts of the plant which, during the continued life of the parent, assisted in its vital functions, have, by reason of its destruction or death, been diverted to new duties. The same part, therefore, is alike adapted to, or at least capable of, nutrition and reproduction.

Buds are formed on and around the underground bulbs of a large number of plants; no mode of reproduction is more familiar to our gardeners.

Buds, again, are produced in some cases on the subterranean stems, as in *Stellaria bulbosa*.

In many cases flowers are replaced by bulbils: *Polygonum viviparum* and *bulbiforum*, *Saxifraga cernua*, *nivalis* and *stellaris*, *Juncus alpinus* and *supinus*, *Aira alpina*, *Festuca alpina* and *rupicaprina*, *Poa alpina* and *conisia* are cases in which perfectly formed flowers are often produced, but in which small bulbils frequently, and especially in alpine or arctic regions, take the place of the flowers. (2 Kerner by Oliver, 454.) These bulbils are detached from the parent plant, and throw roots downwards and stems and foliage upwards. A somewhat analogous growth has been found in the *Nymphæa lotus* var. *monstrosa* (Barber, "On a Change of Flowers to Tubers in *Nymphæa lotus* var. *monstrosa*," *Ann. Bot.* iv. 105). After the development of the sepals, instead of the production of petals and stamens there was formed a bud of green leaves, which developed into a tuber from which a young plant arose. In the persistence of the flower's stalk and sepals, this case differs from that presented by such plants as the *Polygonum viviparum*.

Lastly, one of the most interesting cases of vegetative reproduction is that of parthenogenesis, or the production of seeds by the female plant without the co-operation of pollen. This appears to be established beyond doubt in the case of the *Coelebogyne ilicifolia*, and probably in the cases of the hemp the *Mercurialis annua* and *Gnaphalium alpinum*. This mode of reproduction strikes the mind as very remarkable, because it shows that even in very highly organised plants parts which had been specially provided for reproduction under the stimulus of the pollen cell, still retain the capacity of reproduction even without that stimulus.

It is obvious from these familiar facts that the capacity of reproduction is retained by a great part of the organism in many plants, and that it is not excluded by the fact that the part in question may be highly and definitely organised for some other purpose than reproduction, or that it may be intended, according to the analogy and the common course of nature, for reproduction only after the stimulus of fertilisation.

Conclusions.

The doctrine (to use an ambiguous word) of the alternation of generations may be regarded in several lights: as a compendious statement of facts; as an analogy; as something to be inferred in ancestral forms from existing ones.

If we mean by a generation the life of an independent organism from the time when its whole future was gathered up in one cell, it seems never to represent the facts of vegetable growth; if by it we mean the dependent life of part of an organism from a single cell, it appears to summarise the facts of the full life-history of ferns and mosses, but not of the Rhizocarps or of Phanerogams.

If we regard the doctrine as an analogy, the points in which the analogy breaks down, and the continued recurrence to exceptions to make it agree with the various facts, seem to rob it of much value.

If the alternation of generations be put before us as a fact which the phenomena of existing vegetable life require us to assume in the past, it seems at least doubtful whether more can be justly said than that amongst many modes of reproduction and many schemes of life-history, an alternation of generations in the sense in which it exists in the mosses and ferns may probably be considered as one; but there seems to be nothing to show that it was ever a dominant scheme of life.

The brief review of familiar facts above given seems to tend towards the following conclusions, which I submit with all deference to those better capable of appreciating the question than I am.

(1) That in the language of Prof. Bower, "no fixed and impenetrable barrier exists between sporophore and oophore," but that, on the contrary, the one is capable of passing over to the other, and that the alternation of generations is not an accurate statement of facts or a useful analogy.

(2) That a truer presentation of the facts is to be found in the statement that fertilisation in a plant does not always result in the direct production of a fertilised ovum capable of producing the cormophyte, as in the Characeæ and the phanerogams, but that it may result in the indirect production of a number of fertilised cells, as in the mosses and some fungi, or, as an alternative view of the same facts, in the direct production of a new part of an existing organism.

(3) That (to repeat the foregoing statement in another form) the different generations in the life-history of any given plant are not separate organisms, but different stages or parts of the same organism.

(4) That when the like events can be found in the life-history of different plants, the order of the succession of events is unstable, and that the first may become last and the last first, according as the physiological circumstances of the plant give scope for the action of that reproductive capacity with which the whole plant seems to be endowed.

(5) That this instability exists, even in the sexual act, as regards its place and time in the order of the succession of events.

(6) That the events which occur in the full life-history of a plant admit of short-circuiting or abbreviation, and that in such abbreviated life-histories the one thing which nature appears to desire to avoid is the sexual act, and that the one thing which it appears to desire to preserve is the cormophyte.

(7) That the passage from the life-history of the moss to that of the fern may be accounted for by a transposition in the order of events, and that by such a transposition a moss may be regarded phylogenetically as the direct ancestor of the filmy fern, and the indirect ancestor of all the other ferns.

(8) That, assuming that there is a germ plasm distinct from somatic plasm, and that the presence of the former is essential for the reproduction of the organism, there is evidence of the wide diffusion of the germ plasm, and that no limit to its presence has yet been ascertained.

(9) And lastly, that the reproductive energy operates in plants in such a variety of ways, and under such varying circumstances, as to make it improbable that the facts of reproduction can, with our present knowledge, be reduced to any one scheme, or referred to any single archetype. Edw. Fry.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—On Tuesday, February 16, Convocation decided to confer by decree the degree of M.A. on Dr. J. S. Haldane, Lecturer in Physiology, and on Dr. W. B. Benham, Aldrichian Demonstrator in Comparative Anatomy.

Messrs. W. W. Fisher (C.C.C.), W. Hatchett-Jackson (Keble), W. S. Church (Ch. Ch.), W. Collier (Exeter), S. H. West (Ch. Ch.), J. E. Marsh (Balliol), and G. W. S. Farmer (Balliol) have been elected members of the Board of the Faculty of Medicine.

The following have been elected Members of the Board of the Faculty of Natural Science:—Messrs. C. Leudesdor (Fellow of Pembroke), D. H. Nagel (Fellow of Trinity), E. H. Hayes (Fellow of New Coll.), J. W. Russell (Merton), J. Walker (Ch. Ch.), F. J. Jervis Smith (Trinity), A. Thomson (Exeter, Professor of Human Anatomy), W. W. Fisher (C.C.C.), and V. H. Veley (University).

On Monday, March 1, Prof. E. E. Barnard exhibited some of his astronomical photographs in the Examination Schools.

Mr. A. C. Le Rossignol (Exeter Coll.) has been elected to an Exhibition in Natural Science at Exeter College on the foundation of King Charles I.

Captain W. de W. Abney, C.B., F.R.S., has accepted the invitation of the Junior Scientific Club to deliver the Robert Boyle Lecture for 1897.

Scholarships and Exhibitions have been announced for competition as under:—In Natural Science, at Merton, New, and Corpus Christo Colleges, on July 6, 1897; in Mathematics, at Ch. Ch. and Hertford Coll., on June 2, 1897; in Classics, Mathematics, Modern History, or Natural Science, on April 27, 1897.

CAMBRIDGE.—Nine members of the Syndicate on Degrees for Women have reported in favour of granting by diploma the title of B.A. to women who pass a final Tripos examination after residing at Newnham or Girton for nine terms. They propose that the like grant should be made retrospectively to women who have already taken the qualifying examinations, and that after the usual periods the higher titles of M.A., D.Sc., and D.Litt. should be open to the titular B.A. Lastly, they regard it as desirable that women should be made eligible to degrees in Arts, Law, Science, and Music, *honoris causa*. A minority report signed by five members advocates that special titles such as *Magistra in Litteris* (M.Litt) should be devised for duly qualified women, on the ground that these would remove any disability under which Cambridge women students may labour for want of a formal degree, while it would preclude any agitation for full membership of the University, with its concomitants of franchise and governing power. They apparently deprecate, for the same reason, the exclusion of students other than those of Newnham and Girton from participating in the proposed concession. The reports have yet to be discussed by the whole Senate, and it is not improbable that they may be referred back to the Syndicate.

The Special Boards of Studies concerned with the Natural Sciences Tripos propose that candidates in physics and chemistry be allowed to send in, for the inspection of the Examiners, notebooks showing the records of practical work done by them, and bearing the signature of their teacher as a guarantee of their *bonâ-fides*.

Prof. A. W. Williamson, F.R.S., has been appointed an Elector to the professorship of Chemistry and the Jacksonian professorship of Natural Philosophy; and Mr. M. H. N. Story-Maskelyne, F.R.S., an Elector to the chair of Mineralogy.

According to the lists just issued it appears that while there are only ninety-seven candidates for the Mathematical Tripos (Parts I. and II.), there are 144 for the two parts of the Natural Sciences Tripos in the Easter Term.

By the will of the late Dr. Robert H. Lamborn, states the *American Anthropologist*, the Academy of Natural Sciences of Philadelphia has been bequeathed his entire estate, aggregating about 40,000*l.*, the interest of which is to be used for biological and anthropological research.

By the will of the late Mr. George Gordon Nicol, states the *British Medical Journal*, important bequests have been left to Aberdeen. Of sundry trust funds, the income on which accrues to his wife during her lifetime, 20,000*l.* are to be in trust for the University of Aberdeen, to found bursaries and scholarships or exhibitions to the English Universities, for Aberdeen students who are natives of Aberdeenshire.

THE following are among recent announcements:—Dr. Edwin Klebs, the well-known German pathologist, appointed to be professor in the Rush Medical College, Chicago, will also occupy a position in the post-graduate medical school of the University of Chicago; Dr. A. C. Abbott, Professor of Hygiene in the University of Pennsylvania, to be chief of the Bacteriological Department of the Philadelphia Health Bureau; Dr. Karl Futterer, Associate Professor of Mineralogy and Geology in the Technical High School at Karlsruhe, to be professor; Dr. Pauly, Associate Professor of Applied Zoology in the University of Munich, to be professor, and also director of the Zoological Department of the Forestry Experimental Station at Munich; Dr. Felix to be professor of anatomy at Zürich; Dr. Karl Kaiser to be professor of physiology at Heidelberg.

ON Friday last, at a meeting of the delegates from institutions named in the report of the Cowper Commission on the University of London, Lord Lister moved the following resolution:—"That this meeting of delegates represents to Her Majesty's Government the great injury caused to the educational interests of the metropolis by the delay in establishing a teaching University for London, and urges upon them the necessity of taking immediate steps for the constitution of a statutory commission for the reconstruction of the University of London on the lines of the recommendations of the Cowper Commission." The motion was seconded by Prof. Rücker and carried unanimously. Lord Lister said that his varied experience had shown him how much more beneficial to the progress of medical science and to the instruction of students the Scottish system of teaching and examination was than the purely examinational system of the University of London. After remarks in support of the resolution by other speakers, Lord Reay said that in no other country in Europe would such a company of distinguished men of science and of learning have urged on its Government the necessity of founding a teaching University without the Government at once acceding to their wishes.

EVERY one interested in educational matters knows that each report of the U.S. Commissioner of Education is a mine of information upon educational progress throughout the world. The seventh of these annual reports, referring to events and developments during the year ending June 30, 1895, has just come to hand. It is in two volumes, each running into about twelve hundred pages. Though largely taken up with information referring to elementary schools, higher education is very fully dealt with, both statistically and from the pedagogical point of view. The movement for the admission of American students to French universities is surveyed. A measure has been secured which enables students from the United States to enter the faculty of sciences in French universities as candidates for the degree of licentiate on the basis of their American diplomas. After the degree has been attained, the doctor's degree may be secured on substantially the same terms as in Germany. An account is given of continuation and trade schools in Germany, especially in Berlin. It shows how the German school authorities endeavour to prepare for skilled labour, and thus increase the productiveness of their sources of wealth. A chapter on the condition of the agricultural and mechanical colleges in the United States, endowed by the national land grants of 1862 and 1890, is preceded by an historical review of early attempts to introduce the subjects of physics, chemistry, manual arts, and agriculture into schools. There is also a chapter on American medical schools. Information on many other educational subjects will be found in the recently-published report.

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, February.—Water at unusually low temperatures. On November 30, the observer at Camden Square found that the water supply for the wet bulb thermometer on a Glaisher screen was not frozen, though the air temperature was 29·1°, and that congelation would not take place after stirring the water. The water was afterwards subjected to chemical examination; the somewhat negative character of the results seems to show that the exposure to a smoky atmosphere in the open glass vessel had increased the tendency to resist freezing. In another glass vessel on the same screen, more protected from radiation, but more exposed to the wind, the water was frozen into a solid mass.—An attempt to determine the velocity equivalents of wind-forces estimated by Beaufort's scale, by R. H. Curtis. This is a summary of a paper read before the Royal Meteorological Society on December 16, 1896, a notice of which has already appeared in our columns. In the discussion which followed, the opinion was generally expressed that the publication of velocities obtained by the use of the usual factor 3, which assumes that the cups of the anemometer move with one-third of the wind velocity, should be discontinued, the results being considerably in excess of the true values. The revised factor, as deduced by Mr. Dines and others, is found to be nearer 2·2.—A tornado at Este's Park, Colorado, by H. C. Rogers. The height of the Park is 7500 feet above sea-level. The chief interest in the paper lies in the usual impression that tornadoes are generally restricted to the plains. Information upon this point is desirable, also as to whether they escape notice owing to their force being less, or whether they occur less frequently because the conditions of heat and moisture necessary for their formation do not exist.

Memoirs (Trudy) of the St. Petersburg Society of Naturalists, vol. xxvi., 1896: Section of Botany.—Can algæ assimilate free nitrogen? by P. S. Kossovich.—It is known that Schloesing and

Laurent had proved, in 1892, that soil which contains both algæ and bacteria does assimilate free nitrogen from the atmosphere, but it was desirable to ascertain how far pure algæ, without bacteria, are endowed with the same capacity. This work was undertaken by the author, under the guidance of A. Koch. The result is that pure cultures of *Cystococcus* and, very probably also, of *Stichococcus* do *not* assimilate free nitrogen. On the contrary, a soil which contains both algæ and bacteria can be enriched to a considerable extent with nitrogen absorbed from the atmosphere. The algæ aid, in such cases, the bacteria in their work of assimilation, as they enrich the soil with hydrocarbons, which are required for the growth of the former. A sort of symbiosis thus takes place between the algæ and the bacteria; but, of course, it would be premature to maintain that no algæ whatever can absorb free nitrogen.—Materials for the Flora of the Turkestan Highlands: the Basin of the Zerafshan, by V. Komaroff. This is a detailed work in which a list of 362 species is given, and is preceded by a general sketch of the vegetation of the valley of the Zerafshan (this latter has already been referred to in a previous issue).—Physiological researches into the growth of elementary organisms, by K. A. Stameroff. The influence of light on the speed of growth of hyphæ of *Mucor*, *Penicillium*, and *Saprolegnia*, of rhyzoids of *Marchantia polymorpha*, and of the pollen of various plants, were studied, and complete results, both positive and negative, were obtained.—An addition to the lists of the flora of the Government of Novgorod, by V. Komaroff; and on the same flora, by A. Kolmovsky and A. Antonoff.

Vol. xxvi. 2, 1896: Section of Zoology and Physiology.—Some observations on the embryonic development of *Neomysis vulgaris*, var. *Baltica*, by Jul. Wagner, with five plates, fully summed up by the author in German.—Observations on spermatogenesis with spiders, by the same author, with two plates, and also fully summed up in German.—Note on the influence of a permanent current on the muscle irritated through the nerve, by A. D. Grigorieff.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 4.—"On the Condition in which Fats are absorbed from the Intestine." By B. Moore and D. P. Rockwood. Communicated by Prof. E. A. Schäfer, F.R.S.

In these experiments the solubility of the mixed fatty acids of beef suet, mutton suet, and lard in the bile of ox, pig and dog was determined at body temperature, and found to vary between 1 and 7 per cent. That the greater part of the fatty acids is *not* dissolved as soap is shown by the ready solubility in ether of the precipitate thrown down on cooling, and the ease with which it saponifies with sodium carbonate.

Undoubtedly a small portion of the fatty acids added combines with the alkali of the bile to form soaps, for the reaction, which is at first alkaline to litmus, changes afterwards, becoming strongly acid. The solubility of the mixed fatty acids in bile is only in part due to the bile salts, for a more concentrated solution of these than bile itself did not dissolve nearly so large an amount of fatty acids. And, again, mere removal of the "pseudo-mucin" from bile greatly diminishes its solvent action on fatty acids, although the "pseudo-mucin" redissolved in sodium carbonate has no solvent power.

The contents of the intestine were removed in dogs during fat absorption and filtered. The filtrate decomposed and dissolved neutral fats at the temperature of the body. This effect is due to the simultaneous action of pancreatic juice and bile. A similar result was obtained by acting on neutral fats with pancreas and bile, while pancreas alone decomposed the neutral fats into fatty acids, but did not dissolve them.

The solubilities stated above are quite sufficient to account for the removal of all the fat of the food from the intestine as dissolved fatty acid, since they exceed the concentrations found in the intestine of other materials, such as sugars and albumoses, which are removed in solution. Other experiments, however, on the reaction of the intestine during fat absorption, lead the authors to think that all the fat is not absorbed as dissolved fatty acids, but that these are replaced to a variable extent (in some animals to a very large extent or completely) by dissolved soaps.

The reaction of the contents of the small intestine to litmus during fat absorption in the dog is at the pylorus neutral, faintly acid or faintly alkaline; from here onwards the acidity increases, reaches a maximum about the middle of the small intestine, and then becomes less acid, to change to alkaline at a point situated about three-fourths of the way along the intestine. The reaction to methyl-orange and phenolphthalein explains this; the contents are alkaline to methyl-orange from pylorus to cæcum, and, equally completely, acid to phenolphthalein, showing that the acid reaction to litmus in the upper part is due to weak organic acids, while the alkaline reaction in the lower part is due to fixed alkali, accompanied by dissolved carbonic acid. The alkaline reaction to methyl-orange in the upper part, where it is acid to litmus and phenolphthalein, shows that in that part there is an excess of bases, above that quantity necessary to combine with all the inorganic acids, which are combined with weak organic acids (probably fatty acids). In the lower fourth or thereabouts, where the reaction is alkaline to litmus, there cannot be any fatty acids present in solution. Therefore any fat that is absorbed as free fatty acid must be taken up from the upper three-fourths of the intestine, where the reaction is acid to litmus.

In the white rat during fat absorption the contents of the small intestine is alkaline to litmus from pylorus to cæcum, and is never acid for a greater distance than two or three inches below the pylorus; in this animal, therefore, nearly all the fat must be absorbed in solution as soaps.

February 11.—"On the Regeneration of Nerves." By Robert Kennedy, M.A., B.Sc., M.D., Glasgow. Received January 7.

The author gives the clinical histories of four cases of division of nerves, in which restoration of function had not occurred at periods varying from a few weeks up to eighteen months from the date of section. Secondary suture was performed, and the sense of pain commenced to return in from two to five days, and sensation speedily became perfect. Motion was not recovered till a late date.

He concludes that this early return of function is due to restored conductivity of the divided nerves, and that the theories which have hitherto been advanced to account for return of sensation apart from reunion of the nerve, are inapplicable to cases in which *early* return of sensation occurs from suture, performed after the lapse of *several months* from the time of section. The tardy and imperfect return of motion is explained on the ground that the muscles have undergone great trophic change, as a result of long separation from their trophic centres.

From the histological changes found in the portions removed at the operations, he concludes:

(1) That there is no evidence of ascending degeneration of the kind described by Krause after interruption of a nerve.

(2) That the old axis-cylinder and myeline sheath are destroyed in the peripheral segment, and in the ultimate portion of the central segment.

(3) That young nerve fibres are developed in the peripheral segment, as well as in the end of the central segment, and that even while there is no connection between the two ends.

(4) That these young nerve fibres originate within the old sheath of Schwann from the protoplasm and nucleus of the interannular segment, the new axis-cylinder being developed from the protoplasm, while the nuclei remain attached to the sides of the new fibres.

(5) That so long as the conductivity of the nerve is not re-established, the development of the young fibres proceeds only to a certain stage, which may be regarded as a resting stage, as the fibres after three and eighteen months respectively present identical characters.

(6) That cicatricial intercalary segments may contain young nerve fibres from end to end without re-establishment of function, if the amount of cicatricial connective tissue in the mass is sufficient to prevent by its pressure the passage of impulses.

February 18.—"Note to the Memoir, by Prof. Karl Pearson, F.R.S., on Spurious Correlation." By Francis Galton, F.R.S. Received January 4.

This note was intended to serve as a kind of appendix to the memoir of Prof. K. Pearson, the author believing that it might be useful in enabling others to realise the genesis of spurious correlation. It was important, though rather difficult, to do so, because the results arrived at in the memoir, which are of serious interest to practical statisticians, have at first sight a somewhat paradoxical appearance.

The diagrams which accompanied the paper show how a table of frequency of the various combinations of two independent and normal variables may be changed into one of A/C, B/C,

where C is also an independent and normal variable in respect to its intrinsic qualities, but subjected to the condition that the same value of C is to be used as the divisor of *both* members of the same couplet of A and B. In short, that the couplets shall always be of the form A/C_n, B/C_n, and never that of A/C_n, B/C_m.

Physical Society, February 26.—Mr. Shelford Bidwell, President, in the chair.—Mr. J. H. Vincent read a paper on the photography of ripples. If mercury is used as the medium, all waves less than 1·3 cm. long come under Lord Kelvin's definition of a ripple; that is to say, they are waves whose lengths are less than such as are propagated with minimum velocity. Vibrations in mercury of about 200 per second and upwards generate waves whose propagation is controlled almost entirely by surface tension, and these waves are therefore classed as "capillary ripples." Their speed of propagation is of the order of about one foot per second. They are invisible owing to their high frequency, and not in consequence of the velocity of their propagation. It is usual to examine them by some stroboscopic method. Mr. Vincent obtains photographs of the disturbed mercury surface by the sudden illumination of an electric spark. The spark is about half a centimetre in length, and it lasts about one two-hundred-thousandth part of a second. Its brightness is increased by an auxiliary spark-gap. The optical arrangement consists of two lenses, one in the path of the incident light, and another to converge the reflected light from the mercury surface into a photographic camera. Ripples are set up in the mercury by a stylus attached to a tuning-fork. For this purpose it is generally sufficient to give a slight blow to the prongs; but when continuous vibration is required, the tuning-fork can be connected by a thread to an electrically-driven fork, as suggested by Mr. Watson. The first photograph shows a series of circular waves, set up by a single stylus attached to a fork vibrating 180 times a second. Fixed points at known distances, just above the mercury surface, enable the wave lengths to be deduced from the photographs; and, as the frequency is known, the surface-tension may be easily calculated. In a second photograph, two styluses are attached to the same prong. Dark lines are seen to radiate from the region between the centres of oscillation; these are the lines of minimum disturbance—hyperbolas, of which the centres of disturbance are the foci. This photograph illustrates "interference" similarly to the optical methods of Young and Fresnel. A third photograph shows the formation of elliptical curves of disturbance, being the loci of the intersection of two series of circles, corresponding one to each of two centres of vibration. Unlike the system of hyperbolas, these ellipses are not at rest, but travel outward from the sources. In order to render these ellipses stationary it would be necessary to change one of the *sources* into a *sink*, towards which the circular waves might converge; the photograph would then correspond to the optical device of M. Meslin, who obtains interference fringes by means of a screen placed between two point centres, one a *source*, and the other a *sink*. The phenomena of interference and diffraction are well shown in a photograph of a point source and a reflecting line. The reflector here is one side of a triangular piece of microscope cover-glass. The interference lines are due to the mutual action of incident and reflected rays; they are analogous to Lloyd's single-mirror fringes. Other photographs exhibit analogues of "spherical aberration" and "forced vibration." Mr. Vincent acknowledged his indebtedness to Mr. Boys for the recommendation of attempting the photography of capillary ripples. Mr. Boys congratulated the author upon the way in which the experimental difficulties had been overcome. The results would bear a good deal of close examination, and they would be found to present analogues of the greatest service in demonstrating the phenomena of acoustics and optics. Such photographs were far better than geometrical pictures drawn by instruments. For example, in the photograph illustrating the regions of minimum disturbance by lines radiating from a two-point source, it was easy to make out the positions where the two series of waves were half a period behind one another. The crests and troughs appeared as a set of dark and light concentric alternating circles, broken up into short arcs by radiating lines, the loci of minimum disturbance; all the crests on one side of any particular radiating line were seen to correspond to troughs on the other side, so that the field of disturbance was mapped out as in acoustics. One set of phenomena yet awaited illustration by this photographic method, and that was "diffraction" from a grating. It might be possible to use as an exciter a comb with chisel-shaped points. He did not think it would be possible to go quite so far as to reproduce analogues of spectral analysis. Since wave-length varies with surface-tension it was possible to vary the wave-length by dropping a little ox-gall or soap solution upon the mercury surface. Mr. Blakesley asked why no reflections occurred from the sides of the mercury retainer. Mr. Boys said the waves were lost at the edges of the meniscus. The mercury was kept in position by an annular ring of thin glass. Mr. Appleyard suggested that the analogue of refraction might be obtained by an alteration of the surface-tension over a small area, by amalgamation or other means. Mr. Vincent thought this could be done, but that it would be very difficult. The President proposed a vote of thanks to the author.—Mr Elder then read a paper, by Mr. Beckit Burnie, on the thermo-electric properties of some liquid metals. The investigation was made with a view to determining the effect of melting upon the thermo-electric properties of certain metals. The metal to be tested is contained in a W-shaped glass tube, of which one limb can be cooled and the other heated. Thus one limb can contain molten, and the other solid, metal. Copper-wires are plunged, one into each limb, and through these connection is made with a galvanometer. The thermal-junctions, therefore, are copper-hot metal, and copper-cold metal. The temperature is deduced from a separate thermal-couple, calibrated by a mercurial thermometer. Curves are drawn coordinating temperature and electro-motive force. It is found that their slope depends upon the rate of cooling or heating of the metals; this is particularly the case with bismuth. The effect is attributed to the variation in crystalline structure of the metal under test, at different rates of solidification. With tin the change is less marked, and with lead it is unnoticeable. At or about the melting points, there is considerable change of slope in the curves. Here, again, the effect is smallest for lead; somewhat greater with tin; and remarkably large with bismuth; the latter changing from an exceedingly active thermo-electric metal to one resembling lead. A great change occurs also with mercury at the melting point, indicating a difference in the Peltier effect between solid and molten metals.—A vote of thanks to Mr. Beckit Burnie was proposed by the President, and the meeting adjourned until March 12.

Linnean Society, February 18.—Dr. D. H. Scott, F.R.S., Vice-President, in the chair.—Mr. J. E. Harting exhibited under a glass case the nest of a wren built of moss in the dried body of a rook which had been hung up as a scare-crow in Gloucestershire. Similar instances of the kind had been recorded (*Essex Nat.* ii. 205 and iii. 25). He called to mind the nest of a swallow in the dead body of an owl mentioned by Gilbert White, and referred to other cases which had been collected by a former President of the Society (Bishop Stanley, "Hist. Birds"). For instances of nests of the hoopoe placed in the desiccated bodies of unburied men, he referred to the experience of Pallas in Russia and of Swinhoe in China.—On behalf of Mr. D. T. Gwynne Vaughan, Dr. D. H. Scott gave the substance of a paper on the morphology and anatomy of certain *Nymphæaceæ*.—Mr. J. H. Burrage read a paper on the adhesive discs of *Ercilla spicata*, Moq.

Entomological Society, February 17.—Mr. R. McLachlan, F.R.S., Vice-President and Treasurer, in the chair.—Messrs. Champion and Jacoby exhibited the collection of Phytophagous Coleoptera made by Mr. H. H. Smith in Grenada and the Grenadines for the West India Exploration Committee of the Royal Society.—Mr. F. C. Adams exhibited rare Diptera taken in the New Forest during the preceding year, and including *Callicera ænea* and *Nephrocerus flavicornis*.—Mr. M. Burr showed an example of an undetermined species of locust taken in the Post Office at Bedford Street, Strand, and six new species of Acrydiidæ of different genera.—The Secretary exhibited a Cicada larva from which a fungus, probably *Cordyceps sobolifera*, was growing, which had been sent to the Society from Venezuela, with an inquiry as to its real nature.—The Rev. Dr. Walker showed a series of Coleoptera, Hymenoptera, and Diptera, collected in the Orkney Islands during the previous season.—Mr Tutt exhibited bred examples of the extreme radiate variety of *Spilosoma lubricipeda*. This variety occurred naturally in Heligoland, and its existence in Great Britain was probably attributable to accidental importation.—Mr. Jacoby and Mr. Champion communicated a list of the Phytophagous Coleoptera obtained by Mr. H. H. Smith in St. Vincent, Grenada, and the Grenadines, with descriptions of new species.

Geological Society, February 19.—The following officers were elected:—President: Dr. Henry Hicks, F.R.S. Vice-Presidents: Prof. T. G. Bonney, F.R.S., Lieut.-General C. A. MacMahon, J. J. H. Teall, F.R.S., and Dr. Henry Woodward, F.R.S. Secretaries: J. E. Marr, F.R.S., and R. S. Herries. Foreign Secretary: Sir John Evans, K.C.B., F.R.S. Treasurer: Dr. W. T. Blanford, F.R.S. The medals and funds were awarded as announced in NATURE of January 14 (p. 256). The President delivered his anniversary address, which dealt with some recent evidence bearing on the geological and biological history of Early Cambrian and Pre-Cambrian times.

EDINBURGH.

Royal Society, February 15.—Prof. Geikie in the chair.—A paper, by Prof. Crum Brown and Dr. Bolam, on the electrolysis of potassium ethyl-sulphone-acetate was read by the former. The electrolysis of this salt takes place in a manner quite analogous to that of potassium acetate, the product corresponding to ethane $(CH_3)_2$ being ethylene di-ethyl-sulphone $(CH_3.SO_2.C_2H_5)_2$.—A paper by Lord Kelvin, on configurations of minimum potential energy in clusters of homogeneous molecules, with application to the theory of crystalline forms, was read by Prof. Tait.—Dr. Beattie described further experiments, conducted by Lord Kelvin, Dr. Smolan, and himself, on the apparent and real diselectrification of solid insulators by flame, by air in contact with white-hot metal, by ultra-violet light, and by Röntgen rays (see p. 343).—Prof. Gibson read a paper on photo-chemical action.—Prof. Tait read a paper on the compressibility of salt solutions. On the hypothesis that the compressibility of an aqueous solution of a salt is inversely proportional to its internal pressure, an attempt is made to find the *effective* volume of the dissolved salt, as compared with its volume in the solid form. The experimental data have been employed also to find the nature of the changes in the (nearly constant) ratio (D – 1)/S, where D is the density of the solution, and S the mass of salt in 1 of water. It diminishes slowly with increase of S in all the cases examined, with the single exception of common salt, where it increases slowly. Its actual value has a wide range, being nearly unity for magnesium sulphate, and little more than 0·5 for ammonium sulphate.

MANCHESTER.

Literary and Philosophical Society, February 9.—Dr. Edward Schunck, F.R.S., President, in the chair.—On hypoiodous acid and hypoiodites, by R. L. Taylor. The author referred to the work done on the subject by Schönbein, by Lunge and Schoch, by Schwicker, and, more recently, by Walker and Kay, and pointed out that, when an aqueous solution of iodine is treated with an alkali, a solution is obtained which bleaches much more strongly than chlorine water or hypochlorites. He also investigated the action of aqueous solution of iodine on mercuric oxide, and finds that hypoiodous acid is formed, but possesses very feeble bleaching properties, which, however, are greatly increased by the addition of a small amount of alkali. Hypoiodous acid also appears to be formed by the action of iodine water on certain silver salts: but this solution is much less stable, and loses 90 per cent. of its bleaching power in five minutes.

PARIS.

Academy of Sciences, February 22.—M. A. Chatin in the chair.—Note on the sixth volume of the "Annals de l'observatoire de Bordeaux," by M. Lœwy. The present volume contains a memoir by M. Rayet on the climate of Bordeaux, one by M. Kromm on the Comet 1893 III., and further observations relating to a revision of the austral zones of Argelander.—On the physiological *rôle* of the leucocytes, with especial reference to wounds in the cornea, by M. L. Ranvier. From the observations cited it is maintained that the so-called inflammatory phenomena are really physiological, differing only in intensity from those observed during embryonic development.—On the existence of anode rays analogous to the kathode rays, by M. de Heen.—Photography of the electric radiations of the sun and the solar atmosphere, by the same.—Note on some photographs obtained through plates of various metals, by M. de Sanderval.—Description of the photographic method, allowing of the production of positives in two colours, by M. A. Graby.—On the quadratic integrals of the equations of mechanics, by M. Lévi-Civita.—Remarks on the preceding communication, by M. Appell.—On the formation of the solar system, by M. du Ligondès.—A reply to the objections raised by M. Wolf to M. Faye's theory.—Automatic recording of the bending in the testing of metals, by M. Ch. Fremont.—New method for producing transparent crystals, by M. Ch. de Watteville. If the crystal is kept slowly rotating during its growth, its lustre and transparency are much increased.—On pyrosulphuryl chloride, by M. A. Besson. This substance can only be obtained pure by fractional distillation under reduced pressure. Its boiling point is 53° C. under 15 mm. pressure, 142° C. at 765 mm., and its melting point – 39° C. The reactions with hydrogen bromide, hydrogen iodide, hydrogen sulphide and phosphide are given.—Anethol and its homologues, by MM. Ch. Moureu and A. Chauvet. The method of preparation described is a simplification of the original synthesis of Perkin.—On the soluble oxidising ferment causing the decolorisation of wine, by M. P. Cazeneuve.—On the examination of white wines for coal tar dyes, and the differences between these colours and the caramel colours, by MM. Alb. d'Aguiar and W. da Silva. The reagent employed is amylalcohol acting upon the wine rendered alkaline with ammonia.—Experimental researches on the mechanism of cutaneous hyperemia, by MM. Jacquet and Butte.—On the part played by recurring images in the irradiation phenomena shown by short flashes of light, by M. Aug. Charpentier.—Absorption of nitrogen and hydrogen by the blood, by M. Christian Bohr. The absorption of nitrogen by blood is always somewhat greater than that absorbed by water under similar conditions, and this difference is much increased if oxygen is present along with the nitrogen.—A new generic type of mycomycetes, by M. E. Roze.—The use of sulphate of iron for the destruction of the parasitic cryptogamia of the vine, by M. Croquevielle.—On a crystallised mineral (metabrushite) formed in a leaden coffin, by M. A. Lacroix.—On the Cretaceous beds in the region of Mondégo, by M. Paul Choffat.—The second international ascent of the *Aérophile*, by MM. Hermite and Besançon. The highest point reached was about 15,000 metres, and the minimum temperature – 66° C.

AMSTERDAM.

Royal Academy of Sciences, November 28, 1896.—Prof. vande Sande Bakhuyzen in the chair.—Prof. van Wyhe exhibited a number of anatomical preparations fixed by means of formol, and discussed the conception of the spinal nerve as a complex of two independent nerves.—Mr. Hamburger dealt with the influence of respiration upon the size and shape of the blood corpuscles. In the minute blood-vessels of the tissues the red and the white blood corpuscles undergo a swelling; in the capillaries of the lungs they shrink again. Notwithstanding the swelling the *red* corpuscles show, on microscopic examination, a decrease of diameter. This is to be ascribed to their losing their biconcave flattened form under the given circumstances, and their tendency to assume the globular shape. The swelling is accounted for by the fact that under the influence of CO_2 the proportion of water-absorbing substances increases in a greater measure in the blood corpuscles than in the serum. This brings about a disturbance in the osmotic equilibrium, in consequence of which the blood corpuscles absorb water and swell.—Mr. Jan de Vries presented a paper on geometrical proofs of theorems in number.—Prof. van der Waals presented, for publication in the Academy's *Proceedings*: (1) On behalf of Prof. C. A. J. A. Oudemans, a paper, entitled "Notice sur quelques champignons nouveaux." (2) On behalf of Prof. Kamerlingh Onnes: (*a*) A paper by Mr. L. H. Siertsema, on temperature-coefficients of aneroids. As causes of the usually rather high temperature-coefficients of aneroids are adduced 1° the expansion of the metal, 2° the decrease of the elasticity-coefficients of spring and vacuum box, 3° the expansion of the residual air in the box. An investigation into the consequences of 1° shows that this cause can produce only a small part of the temperature-coefficient. If this cause be left out of account in a first approximation, then the temperature-coefficient λ, when deduced from 2° and 3°, is found to be $\lambda = p(\alpha + \eta) - A\eta$, in which p represents the pressure of the air in the box at 0°, α the expansion-coefficient of air, η the quantity by which the variation of the elasticity-coefficient of the spring is measured $[E_t - E_0 (1 - \eta t)]$, and A the barometric pressure. A comparison with what has been observed experimentally on this point shows that the formula is not in opposition with experience. For a complete numerical comparison, however, more data would be required. (*b*) An account of some further experiments made by Dr. Zeeman in the Leyden Laboratory, concerning the influence of magnetism on the lines of the

spectrum (see pp. 347, 370). (3) On behalf of Mr. J. D. van der Waals, junr., some observations on the law of corresponding states, in which the results of an investigation concerning alcohol and ether by Battelli are compared with those arrived at by Young.—Prof. Lorentz, on the entropy of a gas. The author considers the connection between Boltzmann's H-function and the entropy.—Prof. Schoute, on the position of the sixteen foci of a circular cubic and a bicircular quartic.

DIARY OF SOCIETIES.

THURSDAY, MARCH 4.

ROYAL SOCIETY, at 4.30.—Experiments on the Absence of Mechanical Connection between Ether and Matter: Prof. Lodge, F.R.S.—Second Report on a Series of Specimens of the Deposits of the Nile Delta. Communicated by desire of the Delta Committee: Prof. Judd, F.R.S.—The Palæolithic Deposits at Hitchin and their Relation to the Glacial Epoch: Clement Reid.—Luminosity and Photometry: Prof. J. B. Haycraft.

ROYAL INSTITUTION, at 3.—Greek History and Extant Monuments: Prof. Percy Gardner.

SOCIETY OF ARTS, at 8.—The Mechanical Production of Cold: Prof. James A. Ewing, F.R.S.

LINNEAN SOCIETY, at 8.—On a Trichoderma parasitic on *Peltia epiphylla*, &c.: Dr. W. B. Benham.

CHEMICAL SOCIETY, at 8.

SANITARY INSTITUTE, at 8.—Objects and Methods of Inspection: Dr. J. F. J. Sykes.

CAMERA CLUB, at 8.15. Captain Abney, C.B., F.R.S.

FRIDAY, MARCH 5.

ROYAL INSTITUTION, at 9.—Some Curiosities of Vision: Shelford Bidwell, F.R.S.

GEOLOGISTS' ASSOCIATION, at 8.—Some Properties of Precious Stones: Prof. Henry A. Miers, F.R.S.

SATURDAY, MARCH 6.

ROYAL INSTITUTION, at 3.—Electricity and Electrical Vibrations: Lord Rayleigh.

ESSEX FIELD CLUB (at Buckhurst Hill), at 7.—The Post-Pliocene Non-Marine Mollusca of Essex: A. S. Kennard and B. B. Woodward.—Variation of Lepidoptera: J. W. Tutt.

MONDAY, MARCH 8.

IMPERIAL INSTITUTE, at 8.30.—Imperial Aid to Solar Research, with an Account of Recent Eclipse Expeditions: J. Norman Lockyer, C.B., F.R.S.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Recent Discoveries South of Hudson Bay: Dr. Robert Bell.

SANITARY INSTITUTE, at 8.—Factories, Workshops, and Offensive Trades: Prof. A. Bostock Hill.

CAMERA CLUB, at 8.15.—Some Recent Investigations relating to X-Ray Work: Campbell Swinton.

TUESDAY, MARCH 9.

ROYAL INSTITUTION, at 3.—Animal Electricity: Prof. A. D. Waller, F.R.S.

ROYAL HORTICULTURAL SOCIETY, at 1.—Microscopic Gardening.

ANTHROPOLOGICAL INSTITUTE, at 8.30.

PHARMACEUTICAL SOCIETY, at 8.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Papers to be further discussed: The Main Drainage of London: J. E. Worth and W. Santo Crimp.—The Purification of the Thames: W. J. Dibdin.—Paper to be read, time permitting: The Mond Gas Producer Plant and its Application: H. A. Humphrey.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Demonstration on the Making of Pictures: W. L. Wyllie.

ROYAL VICTORIA HALL, at 8.30.—Cyprus: A. H. Smith.

WEDNESDAY, MARCH 10.

SOCIETY OF ARTS, at 8.—The Prevention of Fires due to the Leakage of Electricity: Frederick Bathurst.

GEOLOGICAL SOCIETY, at 8.—Volcanic Action in Guatemala in relation to Earthquakes in the British Isles: A. Gosling.—The Red Rocks near Bonmahon on the Coast of Co. Waterford: F. R. Cowper Reed.—On the Depth of the Source of Lava: J. L. Lobley.

THURSDAY, MARCH 11.

ROYAL SOCIETY, at 4.30.

ROYAL INSTITUTION, at 3.—Greek History and Extant Monuments: Prof. Percy Gardner.

SOCIETY OF ARTS, at 4.30.—Prevention of Famine in India: Sir Charles Alfred Elliott, K.C.S.I.

MATHEMATICAL SOCIETY, at 8.—On a Law of Combination of Operators bearing on the Theory of Continuous Transformation Groups: J. E. Campbell.—A System of Circles associated with a Triangle: Prof. Steggall.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—On some Repairs to the South American Company's Cable off Cape Verde, 1893 and 1895: H. Benest.

CAMERA CLUB, at 8.15.—Forty Years Mountaineering: Hon. Justice Wills.

FRIDAY, MARCH 12.

ROYAL INSTITUTION, at 9.—The Source of Light in Flames: Prof. A. Smithells.

PHYSICAL SOCIETY, at 5.—A Mechanical Cause of Homogeneity of Structure and Symmetry Geometrically investigated, with special application to Crystals and to Chemical Combination (illustrated by Models): William Barlow.

ROYAL ASTRONOMICAL SOCIETY, at 8.

MALACOLOGICAL SOCIETY, at 8.

ANATOMICAL SOCIETY (University College), at 4.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Inverness Section of the Inverness and Aviemore Railway: H. F. Brand.

SATURDAY, MARCH 13.

ROYAL INSTITUTION, at 3.—Electricity and Electrical Vibrations: Lord Rayleigh.

ROYAL BOTANIC SOCIETY, at 4.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Les Piles Électriques: Ch. Fabry (Paris, Gauthier-Villars).—A Study of the Sky: Prof. H. A. Howe (Macmillan).—Journal of Malacology, Vol. v. (Dulau).—The Universal Electrical Directory, 1897 (Alabaster).—Whitaker's Titled Persons, 1897 (Whitaker).—Remarkable Eclipses: W. T. Lynn, 2nd edition (Stanford).—Remarkable Comets: W. T. Lynn, 5th edition (Stanford).—Celestial Motions: W. T. Lynn, 9th edition (Stanford).—Relics of Primeval Life: Sir J. W. Dawson (Hodder).—Domestic Science Readers: V. T. Murché, Book v. (Macmillan).—Le Cause Première: F. Ferrière (Paris, Alcan).—A New Poultry Guide for British Farmers and others: K. B. Baghot-De la Bere (Seeley).—Untersuchungen über den Bau der Cyanophyceen und Bacterien: Dr. A. Fischer (Jena, Fischer).—Calendario del Santuario di Pompei, 1897 (Valle di Pompei).—Contributions to the Analysis of the Sensations: Dr. E. Mach, translated by C. M. Williams (Chicago, Open Court Publishing Company).—Researches upon the Antiquity of Man: H. C. Mercer (Ginn).—Vorlesungen über Mathematische Physik: J. Kirchhoff, Vierte Auflage, herausgegeben von Prof. Dr. W. Wien, Erster Band: Mechanik (Leipzig, Teubner).

PAMPHLETS.—Report for 1896 on the Lancashire Sea-Fisheries Laboratory at University College, Liverpool (Liverpool).—The Culture of Vegetables for Prizes, Pleasure and Profit: E. K. Toogood (Ulverston, Holmes).

SERIALS.—Familiar Wild Flowers: F. E. Hulme, Part 1 (Cassell).—English Illustrated Magazine, March (1898 Strand).—Longman's Magazine, March (Longmans).—Himmel und Erde, February (Berlin).—Chambers's Journal, March (Chambers).—Contemporary Review, March (Isbister).—Good Words, March (Isbister).—Sunday Magazine, March (Isbister).—Transactions and Proceedings of the Botanical Society of Edinburgh, Vol. xx. THE NEED OF ORGANISING SCIENTIFIC OPINION.[1]

II.

WHATEVER may be the deductions from statistics, it cannot be denied that, as a rule, the attitude of our manufacturers has hitherto been antagonistic to the introduction of a scientific element into our industries; and it is beyond question that the country at large has never learnt to favour the introduction of such an element into our affairs generally.

Admitting that our strongly-marked individuality, our insular habits and prejudices, over-reliance on our powers, and our prosperity and unchallenged commercial preeminence throughout a long period, in some or even a large measure account for our worship of King Rule of Thumb and our apathy as a nation to science, we must go further to find the full explanation.

There can be no doubt that such apathy arises from the fact that "the idea of *science* has been absent from the whole course and design of our education"—words used thirty years ago by Matthew Arnold. It is still true that, as the same writer said, "we hardly even know the use of the word science in its strict sense, and only employ it in a secondary and incorrect sense." We are, in fact, an uncultured nation; which is mainly, if not entirely, the fault of our Universities—for although but a small proportion of English attend the Universities, it is from the Universities that the teachers, as well as the heads of our public schools, are taken, and these set an example which permeates our whole educational system.

Whilst, however, our Universities have *failed* to help us, Germany undoubtedly *owes her success* to her Universities; but hers are real Universities, not "superior boarding-schools"—"places where the youth of the upper class prolong to a very great age, and under some very admirable influences, their school education." They are Universities in which "*Lehrfreiheit* and *Lernfreiheit*, liberty for the teacher and liberty for the learner, and *Wissenschaft*, science, knowledge systematically pursued and prized in and for itself are the fundamental ideas."

Although, in comparing the condition of education in the two countries, Arnold recognised that our Universities were in the main but superior schools, he failed to point out the origin of the difference—that long before he wrote, at the beginning of the century, in fact, they had succumbed to the colleges, so that we had no Universities in the German sense; whilst Germany, happily, was without colleges. But this fact was recognised over fifty years ago by Charles Lyell, who drew special attention to it and discussed the consequences in a most interesting chapter in his "Travels in North America," published in 1845.

Higher education in Germany, in so far as secondary schools are concerned, may be said to date from the reforms introduced by Wilhelm von Humboldt during the brief period (1810–12) in which he was Prussian Minister of Education. Although less well known than his renowned younger brother Alexander, he appears to have been a man of remarkable philosophical power and insight, whose administration of public instruction was clearly based on the fullest understanding of its immense importance, and who recognised that it must be conducted scientifically. We should probably be well satisfied even now if we could secure a Minister of Education, and he were no more than an animated phonograph; one who could repeat with understanding words the Prussian Minister of Education used near ninety years ago—"The thing is *not* to let the schools and Universities go on in a drowsy and impotent routine; the thing is, to raise the culture of the nation ever higher and higher by their means"—words so striking that Arnold attaches them as a motto to his report, would throw the whole body of educational enthusiasts among us into wild delirium, but the country at large would certainly rate him unpractical, if not as a lunatic.

Probably the greatest service to education rendered by von Humboldt was the establishment of a State examination for all schoolmasters; he also, as Arnold points out, took the most important step towards making the *Abiturienten* or school-leaving examination—which plays so vital a part in the German system—what it now is. But von Humboldt was not the only statesman in Germany to take the most enlightened and active interest in the affairs of higher education, and those who followed him in the work of organising public secondary education were able to achieve success because German Universities generally had laid the necessary foundation: otherwise, a satisfactory system could not have been called into life. In witness of this, take the following passage in Carlyle's review of Heeren's "Life of Heyne," in reference to the celebrated scholar's activity, now a century ago, at Göttingen:—

"We have long details of his procedure in managing the Library, the Royal Society, the University generally, and his incessant and often rather complex correspondence with Münchhausen, Brandes, or other ministers who presided over this department. Without detracting from Heyne's skill in such matters, what struck us most in this narrative of Heeren's was the singular contrast which the 'Georgia Augusta,' in its interior arrangements, as well as its external relations to the Government, exhibits with our own Universities. The Prime Minister of the country writes thrice weekly to the director of an institution for learning! He oversees all; knows the character not only of every professor, but of every pupil that gives any promise. He is continually purchasing books, drawings, models; treating for this or the other help or advantage to the establishment. He has his eyes over all Germany; and nowhere does a man of any decided talents show himself, but he strains every nerve to acquire him. And seldom even can he succeed; for the Hanoverian assiduity seems nothing singular; every state in Germany has its minister for education, as well as Hanover. They correspond, they inquire, they negotiate; everywhere there seems a canvassing, less for places than for the best men to fill them. Heyne himself has his Seminarium, a private class of the nine most distinguished students in the University; these he trains with all diligence, and is in due time most probably enabled, by his connexions, to place in stations fit for them. A

[1] Continued from page 411.

hundred and thirty-five professors are said to have been sent from this Seminarium during his presidency. These things we state without commentary; we believe that the experience of all English and Scotch and Irish university-men will, of itself, furnish one. The state of education in Germany, and the structure of the establishment for conducting it, seems to us one of the most promising inquiries that could at this moment be entered on."

So wrote Carlyle in 1828! In truth, a lesson is slowly learnt in this country. And how many of us even now are able to appreciate the value of the services rendered to their nation by Wilhelm and Alexander von Humboldt and by Liebig, and the way in which they have been the true founders of Germany's industrial success—the Moltkes of scientific method.

One of the requirements of a teacher who is a candidate for the Government certificate of *Oberlehrer* in Germany is that he has spent *at least three years* in study at one or more of the Universities; and in the memorandum submitted by Mr. Findlay to the late Secondary Education Commission, we are told that most candidates spend four, many five years there, before presenting themselves for the test. I cannot discover that they are required to prove capacity to take part in the school games—either cricket or football—the primary qualification in an English secondary schoolmaster, if I am not wrongly informed. The difference appears marvellous when we note the extraordinary extent to which the teacher is required to prepare himself for his office in Germany and then reflect on the conditions prevailing here—on the fact that but a few months ago, through a great Royal Commission, we openly confessed to the world that we had absolutely no organisation of secondary education, no check whatever on the competency of the teachers in our schools; and the indifference with which such disclosures have been received, shows what is still worse—that as yet we have no public opinion formed throughout the country which can be brought into operation to enforce the necessary changes.

Nor is this surprising when we consider what our Universities have done for us. To take the case of Oxford. At the close of last century, owing to the operation of causes which cannot be considered here, both teachers and students were thoroughly demoralised, and it became necessary to introduce drastic reforms: examinations having proved useful in some few of the colleges in maintaining orderly habits, to improve matters, in 1800 an examination statute was enacted for the University; but it soon turned out that this had been so framed that it was to be worked by the College tutors, on whose behalf the range of studies was advisedly restricted, all the more progressive branches of knowledge being excluded. As Lyell tells us, the new statute did not pass without a severe struggle. The rector of Lincoln College, in particular, opposed it, as a measure that would extinguish all "thirst of knowledge." "There would thenceforth," he said, "be no *University* at all, but a system of cramming and partial teaching, after which the student would go out into the world with a narrow mind and darker understanding." Never was prediction more thoroughly fulfilled!

It is clear, indeed, that there was "wisdom" at disposal even in those black days; and had wisdom been allowed to govern, the nation might now have been in a very different position. Instead, the horrible system of competitive examinations was allowed to grow up, and worst of all, a new aborted species of teacher, the "coach" or "crammer" was evolved, and the highly lucrative business of "cramming" was established.

"The examinations for degrees were made more and more stringent, and emulation at length stimulated to so high a pitch that health was often sacrificed in the effort to gain the prize. Useful habits of application were often acquired, but the system was not calculated to foster a love of knowledge for its own sake. To some there was even danger of injury both bodily and mental; for if they succeeded, they were tempted to believe that they had already achieved something great; if they failed, their abilities were underrated, both by themselves and their contemporaries."

Notwithstanding the many changes introduced within recent years, whereby some of the defects which Lyell deplored have been remedied, these words of his still afford an accurate presentment of the state of affairs. Moreover, the professoriate still occupy an entirely subordinate although an improved position: for how can they be otherwise than mere mechanical units in a system so long as we fail to recognise that the sole aim of University education should be to develop faculties and to give training in research—so long as "students are treated more as boys and children than as men on the very point of entering on their several duties in life, and who ought, without loss of time, to be acquiring habits of thinking and judging for themselves." We are so absolutely given over to dogmatic and didactic methods of teaching in order to meet the inexorable requirements of examiners, that research work is an entirely post-graduate exercise—a luxury in which but very few indulge, therefore, and the consequence is that a nation priding itself on individuality and originality has an educational "system" in which everything operates towards deadening and maiming the spirit of inquiry, of self-helpfulness, and of thoughtfulness.

How different is the University system abroad. There examinations occupy an entirely subordinate position. From the outset, the student has forced upon him the fact that he cannot gain admission to the degree examination until he has completed a satisfactory thesis embodying some piece of original work; his *Arbeit* is the one absorbing subject of contemplation filling his mind, and the almost daily topic of conversation; and knowing that he cannot count on completing it in any fixed period, and desiring to economise time as much as possible, he devotes himself to his preliminary studies with assiduity and care in order that he may as early as possible secure the necessary permission to commence research. The work accomplished may often be very trivial as a contribution to science, but this matters little: the spirit it evokes is the main consideration—of chiefest importance is the fact that thoughts are always directed forwards with the desire to solve a problem, and that instead of attention being confined to text-books original literature is freely consulted and studied.

It is not surprising that teachers so trained have evoked in turn the proper spirit in their pupils, and that

with such material at their disposal manufacturers have been successful in maintaining their businesses fully abreast of the times.

The post-graduate career is equally different abroad. A graduate is not worshipped as a young god because he happens to have passed examinations with distinction, nor is he damned for life by being termed a second or third class man because he did indifferently well. Nor is he a prig, for although sufficiently proud of being dubbed "*Herr Doctor*," he knows full well that his future success depends on what he does, not on what he has done in some examination. In fact the examination is forgotten almost as soon as over, and if a professional career at the University be adopted, a man has to work very hard for every step of promotion, and is rewarded only if he manifest originality and activity in research.

And manufacturers have also recognised that they cannot expect to obtain all the material they need ready made from the Universities ; the true technical school in Germany is in connection with the works, each of which has its research department, in which men certified by the Universities as likely to do well are set to work under competent leaders and gradually learn to do what is required of them in practice: those who manifest technical skill being gradually drafted off into the works proper. The English manufacturer too often expects the scientific assistant he engages to be already conversant with the industry—to be a practical man ; he will rarely be at the pains to educate his staff. He derides college-bred material, and yet will do nothing towards producing a genuine article.

It is clear that if we are to fit ourselves to carry on the work in the world we have undertaken, and to justify our having taken so vast a burden of imperial responsibility on our shoulders, an entire reform of our educational system, starting from the Universities, must be brought about. We have long since reached the point "where toleration sinks into sheer baseness and poltroonery"; and we must no longer allow mediocrity to be our ideal. The attempt must be made to awaken the public generally to a more thorough understanding of the position in which the country is placed. It must be shown that we also have an "aristocracy of talent" capable of advising honestly and well and with understanding ; that the methods hitherto adopted have too often been unsound ; but that sound methods are now available, and their use must be insisted on. If those who are capable of working in such a cause—and there are very many—will but cooperate, there need be no great delay in formulating and carrying out the changes that are most urgently and imperatively called for : but how are we to effect the necessary organisation of scientific opinion, and secure that its decisions shall be carried into practice? It will be very difficult, and yet it must be done, and without delay. It can only be done if—to use words uttered by Helmholtz—"each of us think of himself, not as a man seeking to gratify his own thirst for knowledge, or to promote his own private advantage, or to shine by his own abilities, but rather as a fellow-labourer in one great common work bearing upon the highest interests of humanity." HENRY E. ARMSTRONG.

(*To be continued.*)

THE GASES OF THE ATMOSPHERE.

The Gases of the Atmosphere: the History of their Discovery. By William Ramsay, F.R.S., Professor of Chemistry in University College, London. Pp. 240. (London : Macmillan and Co., Ltd., 1896.)

THE reading public will be grateful to Prof. Ramsay for this book, for he has explained in a simple and attractive manner the nature of the great discovery about which they have heard much and understood little ; and besides telling the story of argon, he has woven it into a history of the great discoveries of the past concerning the chemistry of the atmosphere. We believe that the book will be acceptable also to more scientific people who desire to gain a clear idea of the problems connected with the new gas.

One of the peculiarities of the discovery of argon is the entire absence of anything about it of the "practical" kind, present or prospective. It is so far a mere scientific discovery, and has no telephone or bone-photographing features to arouse a hollow intellectual interest. A book likely to enlist the public sympathy for scientific research, irrespective of its practical application, is to be heartily welcomed, and is probably no less a need of the times than it was a generation since. It is not well that the public esteem for physics and chemistry should depend wholly on a dim appreciation of their commercial value.

The account which Prof. Ramsay gives of the earlier discoveries is very readable, abounding with quotations from the original memoirs, and affording pleasant glimpses of the lives and characteristics of the philosophers concerned. The volume is embellished with a number of portraits, the honour of appearing in the frontispiece being accorded to Stephen Hales. This selection appears surprising, not only because of the slender connection of the work of Hales with the chemistry of the atmosphere, but from the feeling that in a book dealing with the history of the air in special relation to argon the conspicuous figure is that of Henry Cavendish. The merits of Cavendish have indeed been fully recognised by Lord Rayleigh and Prof. Ramsay in their Royal Society memoir, and the statement "that, if there is any part of the phlogisticated part of our atmosphere which differs from the rest and cannot be reduced to nitrous acid, we may safely conclude that it is not more than $\frac{1}{120}$th part of the whole," will remain for ever memorable. It was the same respect for minutiæ and strict loyalty to experiment as are embodied in the foregoing words, that led Lord Rayleigh, rather more than a century later, to raise again the question whether any part of the phlogisticated part of our atmosphere differs from the rest. The habitual attitude of chemists towards the clue contained in the above words of Cavendish is shown very well by the following passage from Dr. G. Wilson's "Life of Cavendish": "He proceeded to test this by trying whether a given volume of the phlogisticated part was entirely converted into nitric acid by explosion with oxygen. *He found that it was*, and thus supplied a demonstration of the homogeneous nature of nitrogen such as none of his contemporaries could have given."

The last hundred pages of the book contain an account of the discovery of argon, and of the physical and

chemical properties of the new gas. Prof. Ramsay explains clearly the splendid initiatory work of Lord Rayleigh on the density of the simple gases, and then records the successive steps by which the disturbing element was tracked and isolated. Though told in the plainest way, this story cannot fail to prove of dramatic interest even to the non-scientific reader. The account of the properties of argon, and of the difficulties which it raises in respect to the classification of the element, is in a more difficult strain than the rest of the book, and it is possible that a somewhat more extended treatment of the subjects of specific heat and the periodic law would have helped the general reader to a better understanding of the problems presented. At the same time it is right to say that, considering the bounds within which it is compressed and the difficulty of the subject, the account is very lucid, and it will be valuable to all readers who have some acquaintance with science.

In the last few pages of the book Prof. Ramsay gives some play to his scientific fancy, and attempts to offer an explanation of the anomaly presented by argon in respect to the periodic law. He concludes as follows:—

"It therefore appears to me not impossible that the mass of the atoms may be affected by the various and different properties which they possess, some to a greater, some to a lesser extent. It must be admitted that atoms differ from each other in the readiness with which they combine with those of the same kind to form molecules; and that molecules of different elements differ from each other in their capacity to form molecular aggregates. Take for example such cases as cæsium and fluorine, each intensely active, but towards different objects: cæsium the most electro-positive of the metals, and fluorine the most electro-negative of elements. Surely their activity must be due to some cause which cannot but exert influence on their other properties, such as their mass and their gravitational attraction, as it doubtless has influence on their specific heats and on many of their other physical properties. And contrast these instances with helium and with argon the most indifferent of substances, the atoms of which are unwilling to pair even with themselves; it is hardly conceivable that these peculiarities should leave their other, and, as we are in the habit of thinking, invariable, properties unaffected. I venture to suggest that these powers of combination, due to some configuration or to some attractive force, tend to lessen the gravitational attraction by which we measure their atomic weights; that helium and argon, which possess little, if any, of such power to combine, show what may be termed the normal atomic weights, inasmuch as their gravitational attraction is subject to no deduction attributable to their reacting powers."

We cannot reproduce the considerations which lead up to the expression of this remarkable conjecture, and can therefore hardly do the author justice. Prof. Ramsay describes his suggestion as of a wholly speculative character. He expresses his "firm conviction that no true progress in knowledge has been made without such speculations."

With this last statement in itself we are not inclined to disagree; the mind, baffled by difficulties in the paths of orthodoxy, may well be allowed to have its flights and seek more open ways, and there is a well-recognised scientific use of the imagination. But it is impossible to appraise any such speculation as the one before us, and we venture to think that it is rather presented as a *finale* to an interesting story—a sort of last chapter where all ends happily—than intended for scientific criticism. Prof. Ramsay likens it to the doctrine of phlogiston; and certainly the assumption of "levity" is a point of resemblance. Otherwise we think the comparison unfair to the phlogistians. The idea of phlogiston was doubtless at its birth a speculation, but in science it ranks as a working hypothesis that guided several generations of investigators from point to point in their inquiries, that linked together a vast number of facts, and that even to the acute and sober mind of Cavendish appeared to throw as good a light on facts as the newer doctrine of Lavoisier. If Prof. Ramsay's speculation proves fruitful, it may claim kinship with Becher's; but hardly till then. The author recognises this, no doubt, as fully as any one. Meanwhile the situation between argon and the periodic law is not eased in any practical sense, and we are afraid that the book, which in many respects is an admirable exposition of the methods of scientific discovery, may prove somewhat misleading to the general reader in this one particular.

We cannot conclude this notice of a work dealing with the history of chemical discoveries relating to the atmosphere, without remarking upon the momentous part they have played in the development of chemical science. Viewing the discovery of argon in the light of earlier discoveries respecting the air, we feel that it is worthy to rank with the best of them, both in the manner of its inception and of its experimental realisation. The discovery has already raised questions of fundamental interest in physics and chemistry, and there seems no reason to believe that it will not prove as fruitful in important consequences as any of the earlier masterpieces of experimental work relating to the gases of the atmosphere. A. S.

THE FENS OF SOUTH LINCOLNSHIRE.

A History of the Fens of South Lincolnshire. By W. H. Wheeler. Second edition. Pp. 489, and appendices. (Boston: J. M. Newcomb. London: Simpkin, Marshall, and Co.)

THIS book, which is nominally a second edition of a book published in 1868, but has in reality been entirely re-written and enlarged, relates merely to the fens of Lincolnshire, situated between the Steeping River and the Nene, comprising an area of 363,000 acres, and does not refer to the fens of Norfolk, Cambridgeshire, and the adjacent counties, or to the rivers Ouse and Nene, which, with the rivers Witham and Welland, are known as the fen rivers. In fact, the author naturally deals with the fen districts in his near neighbourhood, having resided for many years past at Boston, on the Witham. The history of these fens is traced back to the time of the Britons, and more particularly to the Roman settlement which was made very early in the Christian era; and to the Romans in the time of Severus, are attributed the construction of the first banks protecting the district from the sea, the land being from 1½ to 12½ feet below the level of high-water of spring tides, to which probably the appellations North and South Holland, denoting certain portions of the fens, are due. Lands outside the Roman banks have been gradually raised by the process of warping, or accretion

from the deposit of materials brought down the fen rivers in flood-time, and have then been enclosed and drained. The area of land thus reclaimed from the sea, since the formation of the first sea banks about 1700 years ago, amounts to 63,300 acres, or an average yearly addition of 37½ acres. Mr. Wheeler points out that the reclamations must be gradual, owing to the limited quantity of fertilising alluvium brought down by the rivers, and that the schemes which have occasionally been brought forward for enclosing large areas of the sandy foreshores of the Wash, adjoining the fens, would be financial failures on account of the barren nature of the sands before they are covered over with warp.

The subject is dealt with in seventeen chapters, followed by eight appendices; and it is illustrated by fourteen maps of the various districts, and two diagrams exhibiting the strata, levels, and rainfall of the fens. Unfortunately, no pages are given in the table of contents, which renders reference to the different chapters and illustrations a tedious search; and marginal headings in small print only partially compensate for the absence of top headings to the pages, and the entire omission of notes. A general early history of the fens is given in the first chapter, and the several drainage districts are described in turn; and special chapters are devoted to the river Witham, the river Welland, the estuary and its reclamation, Boston Harbour, and the Witham Outfall, with which the author has long been professionally connected, the geology and water-supply of the fens, and a concluding chapter on the natural history, products, climatology, and health of the district. The inhabitants of the fens have had to maintain a constant struggle with nature, first in rescuing and preserving these fertile lands from the sea, and by degrees increasing their extent by fresh enclosures; and secondly, in improving the drainage of these flat low-lying districts by straightening, enlarging, and embanking the channels of their rivers, and supplementing them by numerous straight drains, so as to prevent the inundation of the lands in times of heavy rainfall. Pumps also have been extensively introduced to remove the water from the lands, and, to assist in the drainage of the district, which, owing to the small fall, cannot be wholly effected by gravitation. Sluices placed across the rivers in the neighbourhood of their outfalls, with gates to arrest the tidal flow, and thus secure the land above from any chance of an inroad of the sea, through breaches in the embankments along the river banks, have naturally, in conjunction with silting in the Wash, produced a deterioration in the depth of the outfalls, which has been detrimental to drainage as well as navigation. The straightening, however, of the outfall channels has effected some improvement; and the formation of a more direct outlet for the Witham, by cutting a new channel for the river, in 1880-84, two and a quarter miles long, through a projecting clay bank below Boston to deep water in the Wash, has effected a great amelioration in the navigable channel between Boston and the sea, and in the outflow of the drainage waters, which latter was at the same time further facilitated by an enlargement of the Grand Sluice above Boston.

The author being an engineer, has perhaps given more prominence to the engineering features of the history of the fens than another writer might have done; but unquestionably the prosperity, and even the existence of the fens are almost wholly dependent on engineering works. The book, however, does not pretend to give detailed descriptions of the works carried out, which have been recorded by Mr. Wheeler and others in engineering publications; and the book will chiefly interest archæologists and topographists, and especially those who live in the neighbourhood of the districts described. Though Mr. Wheeler, as an old inhabitant, has given somewhat too rosy a description of the attractions of the fens on pages 2 and 486-487, where the features of the landscape are banks, drains, windmills, and occasional church towers, and keen north-east winds often prevail through the spring up to June, he shows great interest in the country he resides in, extending to minute details on a variety of topics, and has produced a volume exhibiting considerable labour and research.

OUR BOOK SHELF.

Bacteria of the Sputa and Cryptogamic Flora of the Mouth. By Filandro Vincentini, M.D. Translated by Rev. E. J. Stutter and Prof. E. Saieghi. Pp. x + 239. (London: Ballière, Tindall, and Cox, 1897.)

THIS volume is a collection of three monographs and an appendix, viz. First memoir: On the Sputa of Whooping Cough. Second memoir: Recent Bacteriological Researches on the Sputa. Third memoir: On *Leptothrix racemosa*.

Without in the least wishing to detract from the earnestness, enthusiasm and laudable industry of Dr. Vincentini, we are sorry to have to confess that this book is what, in Germany, would be called an overcome standpoint—*ein überwundener Standpunkt*. Fifteen years ago, prior to the introduction, by Koch, of exact methods of bacteriological study, this book, dealing with the purely microscopic examination as to size and shape of micro-organisms in the sputa and of the mouth, would have had some *raison d'être*; not so at the present time. Everybody knows that if you talk of a bacterial species, of pathogenic and non-pathogenic organisms, you mean not merely the size and shape of a microbe, but that you have studied its biological, chemical and cultural characters, and that you have ascertained whether or not, and under what conditions, it possesses, or is devoid of, pathogenic properties when introduced in one way or another, experimentally or otherwise, into the animal system. Of all this, Dr. Vincentini is quite innocent. To assert, as he does from purely microscopic examination, that a host of microbes—bacilli, cocci, vibrios, and spirilla, occurring in the sputa and in the fluid of the mouth—are all derived from, or are parts of, a single species "leptothrix," requires either tremendous courage, or is due to a want of appreciation of the enormous amount of exact work hitherto accomplished. The discussion in the appendix, by Dr Vincentini, of the views of antiquated authors on spontaneity of origin of infectious diseases, and, further, his extraordinary derivation of the tubercle bacillus, spirillum of relapsing fever, gonococcus and pneumococcus from the indifferent leptothrix, is an anachronism of a curious and, we had hoped, extinct type. E. KLEIN.

Neudrucke von Schriften und Karten über Meteorologie und Erdmagnetismus. Nos. 7-9. Edited by Prof. Dr. G. Hellmann. (Berlin: A. Asher and Co., 1897.)

THESE reproductions in facsimile of classic papers in meteorology and terrestrial magnetism are attractive in appearance, and Prof. Hellmann's introductions and

notes make them most instructive publications. No. 7 of the series contains papers of prime importance in the history of meteorological instruments, viz. the correspondence between Torricelli and Ricci on the measurement of atmospheric pressure, in which Torricelli announced the invention of the barometer (1644); and the paper "Saggi di naturali esperienze fatte nell' Accademia del Cimento," in which the first continuous observations with the thermometer and hygrometer are described. This paper appeared in 1666 and passed through eight Italian editions, and was translated into English (1684), Latin (1731), and French (1754). Prof. Hellmann gives a list of the most important works upon the invention of the barometer, thermometer, and hygrometer, and adds some interesting historical notes.

No 8 of the "Neudrucke," entitled "Meteorologische Karten," contains facsimiles of the first wind-chart, isotherms, isobars, and synoptic weather-map, with an introduction in which the various charts are described. The wind-chart is Halley's (1686); the isotherm map is Humboldt's (1817); and the synoptic chart is Loomis' (1846). Two maps of Le Verrier's show the distribution of barometric pressures on September 7, 10, and 16, 1863, as telegraphically communicated to the Paris Observatory from different parts of Europe on those days; and M. Renous' map (1864) of mean atmospheric pressure over France is given as the first chart of mean isobars.

The discovery of the secular variation of magnetic declination is told in Gellibrand's "Discourse mathematical on the variation of the magnetical needle," which appeared in 1635, and is reproduced in facsimile as No. 9 of Prof. Hellmann's "Neudrucke."

The three reprints are worthy additions to a very attractive and serviceable series.

Colliery Surveying: a Primer designed for the Use of Students and Colliery Manager Aspirants. By T. A. O'Donahue. Pp. 163. (London: Macmillan and Co., Ltd., 1896.)

WITH a view to reducing the number of colliery accidents, the law now requires that an accurate plan shall be kept of the workings of each mine. This has led to increased attention being devoted to the subject of mine surveying. Hitherto, it is true, mine surveying has not kept pace with the advances made in other branches of surveying. Great improvements have, nevertheless, been made during the last decade. Colliery managers are now submitted to a severe educational test before certificates are granted to them, and surveying classes are now held at most mining centres. For elementary students attending such classes, Mr. O'Donahue has written this concise little primer. Taking for granted that his readers have merely a knowledge of arithmetic, he has endeavoured to compress into his pages a complete course of instruction in surface surveying, mine surveying and levelling, together with the requisite preliminary information regarding mechanical drawing, geometry, mensuration and the determination of inaccessible heights and distances. With so comprehensive a scheme, and with so small and inexpensive a book, the instructions are necessarily brief and, for the most part, unaccompanied by theoretical explanations. It is to be feared, therefore, that an elementary student working with this book without guidance might be led to learn by heart details without having grasped principles. Used under the supervision of a capable teacher, however, it should prove useful as an *aide-mémoire* to young students. The absence of an index is a serious drawback, whilst the superfluous section on the mensuration of solids could easily have been spared. Numerous typographical errors in the figures have escaped the author's notice. Thus in the first example, worked out on p. 34, there are three mistakes in one line, and in the next line the correct value of 15° is stated to be 1 in 3·74, whilst in the table of incline measure, on p. 142, it is 1 in 3·73. In that table itself there is often an uncertainty about the final figures; for example, the correct inclines for 3°, 4° and 5° are 1 in 19·08, 14·30 and 11·43 respectively, not 1 in 19·09, 14·29 and 11·42, as stated. On p. 140 the reduced level given is 50·3, but the measurement plotted in the drawing is 55 3. Again, the base line of the Trigonometrical Survey was measured in 1784, not 1874, as stated on p. 29. Trifling misprints of this kind, whilst perfectly obvious to the advanced student, are apt to prove stones of stumbling to the beginner.

The British Mercantile Marine. By Edward Blackmore. Pp. xix + 248. (London: Griffin and Co., Ltd., 1897.)

MESSRS. CHARLES GRIFFIN AND CO., Ltd., in their nautical series, have here a book not only serviceable to the men of the mercantile marine, but interesting and enlightening to those who wish to know the true state of our merchant service, which, to a great extent, and especially in smaller vessels, is manned by foreigners.

The history commences with the infancy of the mercantile marine, giving the different laws passed, the state of trade, the different classes of vessels, and the modes of discipline at various times. Further on, the attention of the reader is drawn to the fact that our mercantile marine is suffering from the want of proper education, in that the examinations held for testing the efficiency of the masters and mates can practically only be passed by them through the medium of a "crammer," who teaches them by rule of thumb, what is taught scientifically to the same class of men in other countries by their respective Governments.

It is pointed out, further, that the apprentice, who is on board to learn his profession, at the commencement of his sea career performs only manual labour, seldom, if ever, having the opportunity of learning the art of navigation as opposed to seamanship; this holds good even for mates of smaller vessels.

The book concludes with a postcript, entitled "The serious decrease in the number of British seamen: a matter demanding the attention of the nation," in which the author, in a few words, enumerates some of the points to which the decrease of British seamen is probably due.

Bulletin of the Philosophical Society of Washington. Vol. xii. 1892–94. Pp. xxix + 567. (Washington: D. C. Jude and Detweiler, 1895.)

THIS volume, though dated 1895, was only received a few days ago. A number of very interesting papers, some of which have been already referred to in the columns of NATURE, are contained in it, among them being the following:—"The Mexican Meteorites," by J. R. Eastman; "Peculiarities in the Rainfall of Texas," by A. W. Greely; "The Origin of Igneous Rocks," by J. P. Iddings; "The Moon's Face, a study of the origin of its features," by G. K. Gilbert; "The Texan Monsoons," by M. W. Harrington; "The Earliest Isoclinics and Observations of Magnetic Force," by L. A. Bauer; "Mean Density of the Earth," by E. D. Preston. Mr. Preston's observations were made at Hawaii by two different methods, one depending upon triangulation and astronomical latitudes, and the other upon the diminution of gravity from the sea-level to the summit of a mountain, as revealed by a pendulum. The former method, carried out on Haleakala, gave for the mean density of the earth the value 5·57; the latter method, carried out on Mauna Kea, gave 5·13 as the density. The adopted mean is 5·35.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dynamical Units.

WITHIN the moderate dimensions of a letter it is hard to give due weight to every aspect of a complicated matter, and while trying to emphasise one side I have somewhat overstated the case, as is evident from the way in which Prof. Lodge has taken me up. I was only considering the teaching of elementary dynamics to engineering students. I do not object to a teacher explaining that inertia is such an important constant property of matter, that equality of inertia is our *definition* of equal quantities of matter. What I do object to is, a common inversion of this, by which equality of inertia is *explained* by saying that the quantities of matter are equal. In addition, I urge that teachers of elementary *dynamics* should call what is usually called mass, inertia, so as constantly to bring before the student the fact that this is *the* property with which the dynamics of motion deals. I do not plead guilty in this to confusing the issues. The issues of Prof. Perry's review have been overlaid with a discussion as to one of the greatest advances of modern physics, namely the possibility of representing physical quantities by algebraic symbols; but I was trying to recall the original issue, as to the way dynamics should be taught to engineering students. Babes must be treated babyishly, and as long as engineering students are what they are now, and have to attend a variety of lecturers, and read engineering books as they are, I agree with Prof. Perry in recommending that the engineer's unit of inertia be used by their teachers. I have already explained that a multiplicity of units is a very minor difficulty to those who have once grasped what it is that is being measured, but I do think it confuses them, while getting these ideas, for one teacher to use one system, and another another system, and for each teacher to call the system of the others by hard names. GEO. FRAS. FITZGERALD.

Definite Variations.

MR. F. A. BATHER, in the January number of *Natural Science*, has some remarks on Prof. Cope's "Factors of Evolution" which seem to call for further comment. The case is cited of sheep taken from Ohio to Texas losing the fine quality of their wool, and this definite variation, due to environment, being apparently inherited and cumulative, in spite of selection by the breeders of those lambs which least present the new character. Such facts as these are not new, and it seems to me that they represent simply a phase of atavism. On July 23, 1890, I was present at a meeting of the Royal Horticultural Society, at Chiswick, and heard Mr. E. J. Lowe give an interesting address on ferns. In the course of it, he told how he had a great number of varieties of the hart's-tongue fern, which, on changing his place of residence, he moved into new and poorer soil. They all reverted to the typical form, and it was not until they were again transplanted to good soil that they consented to exhibit their varietal characters! Now in the case of the sheep, the fine wool of the Ohio breed is not a specific character, but a varietal one produced under domestication; and it is not surprising, therefore, that removal to a locality less favourable, and, perhaps, more resembling that of the original type of the species, should produce reversion. But it is probable that, as in the case of Mr. Lowe's ferns, the varietal character could be made to reappear by transference to the former kind of environment. The precise explanation of such facts as these may probably be found in Dr. Weismann's principle of germinal selection, which has surely been more or less understood for a long time. The sheep is born with two or three distinct possibilities, as to its wool; one locality favours one of these possible developments, one another. It is a case parallel to that of an amphibious *Ranunculus*, which can be made to assume one form or the other, according to the terrestrial or aquatic environment.

It is worth while to add, that here in New Mexico, one frequently sees small, usually pale yellowish-brown, horses, with extremely well-marked leg-stripes. These are descendants of the horses which ran wild in former years over this country; and there can be little doubt, I think, that they represent an atavistic variety.

While it is probable that really new variations are equally in all directions, practically the variation of most organisms is remarkably definite, because so largely atavistic. And these definite atavistic variations may be perpetuated, in new combinations, in new races. It is precisely this which gives rise to "kaleidoscopic characters" in a group. A character may appear here and there, and species may be represented by different combinations of the same characters, as words are composed of combinations of the same letters.

To cite an illustrative instance, the wings of bees present frequently one marginal, three submarginal, and three discoidal cells. The submarginals may be reduced to two, or even to one, and the discoidals to two. All sorts of combinations, as to the number, shape, and size of these cells will be found, but the marginal will *not* be found lacking, nor the first discoidal or first submarginal absent, nor will the number of submarginals be found increased.[1] Really new variations, as new ones running out to form a second marginal or a fourth submarginal, appear in slight degree, but doubtless sufficiently to afford material for selection, under new environment; but the old and common variations may occur suddenly, so that there may even be a radical difference between the opposite wings of the same specimen. Very rarely, a remarkable sport will occur, not in accordance with our expectations, but these are much too rare to have selective value. In other hymenoptera, as the sawflies, the range of common variation is quite different; but still the variations to be looked for in each family are not miscellaneous, but run along certain well-recognised lines. To show that new, not atavistic, variations take definite lines is another matter, and I do not believe it can be done.

T. D. A. COCKERELL.

Mesilla, New Mexico, U.S.A., February 18.

The Coral Reef at Funafuti.

THE report on the coral reef at Funafuti that was read to the Royal Society on February 11, will doubtless be of very great interest to all who have studied the very difficult problems concerning the origin of reefs and atolls.

At the same time, many will wonder why Prof. Sollas characterises the boring as a failure. Scientific expeditions very rarely accomplish all that is anticipated or even expected of them, but they are not necessarily failures in consequence. It is true that the borings at Funafuti could not be carried to a depth of more than 105 feet, and that the structure they revealed was not "what a field geologist might have anticipated"; but they revealed the very important fact that underlying a coral reef of 50 feet in thickness, there was a stratum of sand containing a few coral blocks.

It is perhaps premature to consider, until further details are published, whether this fact supports the views of Mr. Murray or his followers; but what is perfectly clear at once, is that it lends no support to the well-known subsidence theory.

I think it is of importance to call the attention of the scientific public to this at once, because, after dismissing the boring as a failure, Prof. Sollas gives the results of the soundings made in the neighbourhood of the island by H.M.S. *Penguin*, and concludes by the statement that, in his opinion, these soundings support Darwin's theory of coral atolls.

I should not like at this stage to take upon myself the responsibility of saying they do not, but I should like to ask, after the negative evidence afforded by the borings, upon what grounds Prof. Sollas bases his opinions. SYDNEY J. HICKSON.

Owens College, Manchester, February 20.

Two Unfelt Earthquakes.

REFERRING to Prof. John Milne's interesting communication on "Two Unfelt Earthquakes," asking for information as to whether these disturbances have been instrumentally recorded elsewhere, Dr. Copeland requests me to say that an examination of the photographs of the oscillation-curve of the bifilar pendulum at this observatory shows several disturbances on February 7, the first of the dates mentioned by Prof. Milne. These are as follows:—At 7.37 a.m. an abrupt movement of the pendulum towards the north; from 8.24 to 8.41 a.m. a distinct reduction in the intensity of the colour of the photographic

[1] *Melipona* and *Trigona* are exceptional, and in many ways depart widely from the normal type, so that they hardly come within the range of typical bee-modification.

trace, doubtless due to tremor of the mirror, and, though not so well marked, yet quite similar in character to the gaps described in a previous letter (NATURE, No. 1410, November 5, 1896); at 5.32 p.m. another abrupt movement to the north, and a similar one at 1h. 20m. after midnight. The three abrupt movements have been compared with the mean of two measures of the sensitiveness of the instrument, and show tilts in the mirror frame of 1·6, 1·1, and 1·3 seconds of arc respectively. In each case the mirror returned to the normal position slowly after a period of from 2 to 4 hours.

On the other date given by Prof. Milne—February 13—there is only a slight trace of irregularity in the curve, consisting of a bend towards the north at 8h. 2m. a.m., the mirror returning to its original position three hours later.

On dates more recent than those to which Prof. Milne calls attention, several disturbances have been recorded here. Of these the most strongly marked are: an abrupt north movement on February 16 at 8 p.m., and another on the 17th at 3 a.m. On the 18th there is a similar movement to the south at 6.15 a.m., followed by two smaller oscillations in the opposite direction, the three covering a period of 1½ hours. On February 19 there are two well-marked gaps, precisely similar in character to those described in the letter above referred to.

THOMAS HEATH.

Royal Observatory, Edinburgh, March 2.

1892 Captain V. Bóttego obtained no less than eighteen specimens of that most singular rodent, *Heterocephalus glaber*, in one day, at the Wells of Herrer, near Archeisa, in North Somaliland. Sixteen specimens, well preserved in alcohol, were forwarded by him to Marquis Giacomo Doria, and have been distributed to various museums through the learned Director of the Museo Civico of Genoa. In his book ("Il Giuba esplorato," pp. 38–41, Roma, 1895) Captain Bóttego figures the *Heterocephalus*, and also one of their colonies of singular conical mole-hills.

Florence, February 24. HENRY H. GIGLIOLI.

THE CAUCASUS.[1]

LITTLE though the methods and spirit of sport have in common with those of science, each subject is greatly indebted to the other. Our knowledge of the habits of big game is mainly due to hunters; and for the first great advances in mountain cartography and in the study of high mountain regions, we are indebted to climbers. In the early days of the Alpine Club some of its members, at the suggestion of John Ball, placed instruments on summits that were accessible only to trained mountaineers, and thus obtained meteorological records much wanted at that time. Subsequently, another group of members of the Alpine Club turned their attention to the Caucasus, where their explorations resulted in the first accurate knowledge of its lofty summits and its great snow-fields and glaciers. Of the Alpine climbers who have taken part in this work, Mr. Douglas Freshfield was one of the earliest, was the best qualified as a geographer, and has been by far the most persistent. His "Central Caucasus and Bashan" (1869), which has taken place as an Alpine classic, helped to rouse the first interest in England regarding the former mountains; and now, after thirty years' further work has been done, he has collected the principal results into a monograph, which is unquestionably the best illustrated book in the literature of mountaineering.

[1] "The Exploration of the Caucasus." By Douglas W. Freshfield. With illustrations by Vittorio Sella. Imp. 8vo. 2 vols. Pp. xxiii + 278; pp. x + 295; with 3 maps and 76 full-page illustrations, and 2 mountain panoramas. (London: Edward Arnold, 1896.)

The Origin of Manna.

THE note in NATURE, p. 349, concerning the "manna," reminds me of a passage in Daniele Bartoli's "Asia."

Speaking of the island of Ormuz—which is described as one of the places in the world worst supplied in even commonest necessities of life, and scarcely having any water—the historian tells us that "not even thorns and briars could grow on its barren soil; no animals or birds (*sic*) are seen there all the year round, but every morning a dew falls which congeals into grains, has a very sweet taste, and is called 'manna.'"

Now, tamarisks affect sandy soils or brackish shores; and as *T. mannifera* grows in Arabia, it may be that the exudations from the plants were blown from Oman, on the eastern shore of Arabia, across the Persian Gulf; or, perhaps, from the nearer coast of Persia. This would seem to confirm the belief that manna is the product of the tamarisk, and not of a lichen.

Tooting College, S.W., February 26. B. TIMOTHY.

"Heterocephalus glaber" in North Somaliland.

IN reference to the note given in NATURE (vol. lv. p. 301) on the mammals collected in North-east Africa by Dr. Donaldson Smith, it may interest some of your readers to learn that in October

coverers of the Caucasus," occupied largely by reference to the English expeditions, to which our knowledge of its highest peaks is due. He then describes "the characteristics of the Caucasus," comparing the range with the Alps, and referring to the most striking features in its flora, and stating the extent of its glaciers. After a brief summary of the political history of the region, he proceeds to his main task—a description of the principal peaks or groups of peaks, and a narrative of the first and, sometimes also of one or two, later ascents. In the second volume the chapters on the mountains and mountaineering are continued, and include contributions by Messrs. H. W. Holder, J. G. Cockin, Hermann Woolley, and Maurice de Déchy. The chapter in the book of most special interest to naturalists, both from its subject and the originality of its treatment, is that contributed by Prof. Bonney. It deals with "the physical history of the Caucasus," and is illustrated by a geological map prepared by Mr. Reeves. Prof. Bonney points out that the Caucasus agrees more closely with the Pyrenees than with the Alps: for it is approximately

From a photograph by W. F. Donkin.

FIG. 2.—The Zanner Passes.

a single chain formed by an isoclinal fold, and is much simpler than the Alps, both in history and structure. Thus, although part of the Caucasian region was occupied by land at intervals during the Palæozoic and Mesozoic eras, it was not until between the Eocene and the Miocene that a mountain chain was formed there. The height was increased by a second series of earth-movements, which happened in the Pliocene. In structure the main chain consists of a band of gneiss, flanked by crystalline schists, which, at two localities, form the central watershed. On the southern side the schists are succeeded by Palæozoic clay slates, while parallel to the main range, and on both sides of it, there are belts of Jurassic, Cretaceous, and Cainozoic deposits. Some of the later deposits rise to a considerable height on the flanks: thus some fossils found by Sella on the summit of the Laila, prove the presence there of some Neozoic deposit; this is said to be Lower Jurassic or Cretaceo-Eocene. As Fournier's recent section shows that there are Eocene rocks only a little to the south of the Laila, and that they occur as a monoclinal fold, of which the northern limb is lost, there is nothing impossible in the view that the fossils belong to the later period.

Prof. Bonney's lucid sketch of Caucasian history is the first of the appendices, the rest of which include the climbing record, tables of temperature and rainfall, a list of the heights at which the glacier snouts occur, and a very short list of literature. One of the principal features of the book is its illustrations. Most of them are Signor Sella's photographs reproduced by the Meisenbach Company; a few, including one or two of the best, such as the view of Ushba and the Chalaat Glacier, are by the Swan Electric Engraving Company. Mr. Freshfield has accepted photographs, as indispensable in such a work as the present, where precision of detail is required; but he frankly confesses his personal preference for engravings. This, however, as he aptly remarks, is not to be taken as a preference for art to accuracy, but for general truth to local detail. The photographs are so numerous and so superbly reproduced, that they show local detail in extraordinary fulness; and the views are so well chosen, that they are as beautiful as they are instructive, as accurate as they are artistic. By the courtesy of the publishers, two of the half-tone illustrations are here reproduced.

With the exception of the journals of Alpine gymnasts, the average book on mountaineering takes a higher place as literature than that of any other class of travel. The author's literary style is too well known to need any commendation here, and it need only be remarked that the present work ranks with the best of Alpine literature. There is one point, however, which is open to criticism. In his endeavour to avoid using "words of terror," which alarm general readers and break the music of sentences, Mr. Freshfield has not followed any definite system of transliterating place-names. Accordingly, to discover Mr. Freshfield's localities on the recent French map of Fournier, or on any Russian map, is a puzzle that requires ingenuity and patience; while to find his names in a Russian index is sometimes almost impossible. Thus ч is sometimes transliterated *ch*, and at other times *tsh*; ж is rendered as *j* or *dj*; *k* may stand either for the Russian к or х, while *kh* also represents both these

letters. The letter *z* comes from either з or и; *b* or *v* from в; *u*, *y* and *i* from ы; and *a* from а or я; and *e* from е or э. Sometimes the Russian о is given its phonetic equivalent of *a*, but at other times, when it has the same pronunciation, it is rendered by *o*. Hence in retransliterating some of the author's place-names into Russian, there are so many available alternatives that certainty is impossible.

The spelling of place-names, however, is a detail with which the general reader has no concern; but Mr. Freshfield's compromises form pitfalls for the students who may use the volume. With the difficulties of the "scientist" the author has scant sympathy. A current of delightful and subtle sarcasm runs all through the book; and the unlucky "scientist" comes in for all the author's hardest hits and most racy banter. At first sight it appears that the three main sins of the man of science are his narrow specialism, his pernicious habit of publishing "scattered communications" in scientific serials, and his delusion that a climber is not necessarily a geologist. The author, however, fortunately defines the sense in which he uses the word "scientist": he means thereby "a man who bears the same relation to a 'man of science' as a poetaster does to a poet." Perhaps it is a pity that Mr. Freshfield did not make use of the pejorative *-aster*, and then classify writers on Caucasian natural history into "scientists" or men of science, and scientasters. Häckel once grouped into one section of a bibliography, all the works which he regarded as quite valueless. He never repeated this experiment; and Mr. Freshfield might have found the publication of a list of scientasters a more dangerous feat than any of his first ascents in the Caucasus. When we come to definite cases, we find that the man of science is blamed for the sins of those who are not men of science, and are hardly scientasters. Mr. Freshfield is severe on the man of science for the mistakes made in underrating the area of the Caucasian glaciers. He promises, on the principle of *corruptio optimi pessima*, that he will only quote from "writers of authority." Then he proceeds to quote from Keith Johnston and Reclus. But they are compilers and not original authorities; and judging from some of the extracts given, we should think the introduction of the word compilaster is urgently required. The quotations from the "Géographie Universelle" afford an illustration of a devotion to obsolete authorities not unusual among anarchists. If a man of science wanted accurate information about Caucasian glaciers, he would not go to books where the information is given second-hand and often third-hand, but to the series of papers by Zhukov in *Zemleviyedyenie*, or the elaborate monograph by Dinnik in the *Zap. Kavkaz. Otd. Russ. Gheoghr. Obshch.* But we cannot find any reference to either author in the volumes, although we have searched for the latter as Dinnik, Djinnikh, Jinnik, Schinnik, and Finik. So we presume he is either a "scientist" or a quasi-scientist or a scientaster, and that his elaborate monograph only "darkens with vain words" the 130 pages of the serial on which it is printed. The complaint is made that men of science have not always given his climbing colleagues fair credit for the results they have obtained. If climbers had always worked as carefully, and observed as thoroughly as Mr. Freshfield, and if they had possessed the critical geographical instinct shown on every page he has contributed to these volumes, the criticisms in question would probably never have been made. The latest scientific work on the Caucasus expresses full acknowledgment of the work of "les hardis alpinistes anglais." And with the present work before him, no one can doubt the value of the contributions which climbers have made to scientific geography. J. W. G.

THE EXTRACTION OF AN ALCOHOL-PRODUCING FERMENT FROM YEAST.

IT has long been currently taught that the alcoholic fermentation of sugar by yeast differs from the more common hydrolytic processes of the ordinary enzymes, inasmuch as it is intimately associated with, and directly dependent on, the living action of the yeast cell. But some investigators have believed that, notwithstanding the apparent impossibility of separating an alcoholic ferment from the organism, such a body nevertheless exists, and that alcoholic fermentation is thus, after all, only a special case of ordinary enzyme action, although, no doubt, one of peculiar complexity.

These views have just received a remarkable confirmation at the hands of Dr. E. Buchner, who has communicated the results of his researches on this problem in a short but important paper, entitled "Alcoholische Gährung ohne Hefezellen," which will be found in the first number of the *Ber. d. deutsch. Chem. Gesellsch.* for the present year. The author, by pounding up pure yeast with quartz sand, and adding a certain amount of water, was able to squeeze out, under a pressure of 4–500 atmospheres, a liquid which, after thorough filtering, was of an opalescent appearance, and possessed an agreeable yeast-like odour. All care was taken to exclude any organism from the liquid, and it was found that under these conditions it was able to excite alcoholic fermentation in solutions of suitable sugars. Thus, on adding a quantity to an equal volume of cane-sugar, bubbles of carbon dioxide appeared after the lapse of an interval varying from fifteen minutes to an hour. Grape-sugar is similarly fermented, but milk-sugar undergoes no change, just as is the case when living yeast is employed.

One observation is of especial interest, namely, that the addition of chloroform, even up to the saturation point, does not inhibit the fermentative process, although it causes a rapid precipitation of albuminous substances from the liquid. This seems to prove conclusively that we are not here dealing with a body which is still living, in the ordinary acceptation of the term.

If the expressed liquid be heated to a temperature of about 50° C. coagulation occurs, and the power of exciting fermentation is lost both by the coagulum and by the remaining liquid. It was also found that in the active liquid the ferment itself diffuses very slowly, if at all, through parchment-paper (*pergament-papier*).

On the whole, the evidence at present before us seems to indicate that the ferment, which its discoverer has called Zymase, is possibly of a proteid nature. Dr. Buchner believes that this is certainly the case, though until it has been separated from the rest of the heterogeneous substances, some at least of which are proteids, the question as to its real constitution can hardly be regarded as decided.

Buchner, whilst believing that the process of normal fermentation can go on within the body of the yeast cell itself, considers it as yet more probable that the Zymase is actually excreted into the sugar solution by the living organism. At any rate, it would seem that proteids can pass out of the cells into the surrounding liquid, for if the yeast be sown in a slightly alkaline solution of cane-sugar, and some of the fermenting fluid be examined after some hours have elapsed, it is found to contain a considerable quantity of a substance which coagulates on heating, and which is stated to be of an albuminous nature.

This brief sketch of Buchner's work will suffice to indicate not only its great theoretical interest, but also its practical importance in connection with those industries which are more directly concerned with fermentative processes. J. B. F.

KARL WEIERSTRASS.

THE death of Prof. Karl Weierstrass, on February 19 in the present year, has taken from science one of the greatest pure mathematicians of the century. It is now some considerable time since he ceased to deliver lectures as professor in the University of Berlin; the last few years of his life were troubled by broken health. As is indicated by a pathetic reference in the preface to the first volume of his Collected Works, he was obliged to obtain assistance, partly in preparing them for publication, and partly to secure that his intentions with regard to them might be carried out in case of his death. This help was loyally given by friends and former pupils during his life; it may be expected that the same loyalty will now be devoted to completing the series, which will be a fitting monument to his genius. And the appearance of the successive volumes will be eagerly expected and cordially welcomed by pure mathematicians all the world over.

Weierstrass was born at Osterfelde, near Münster, on October 31, 1815; so that at the time of his death he was in his eighty-second year. His first professorship was at Deutsch Krone, the appointment dating as far back as 1842; from that chair he passed, in 1848, to Braunsberg; and thence to Berlin. He was made professor extraordinarius at that University in 1856, and full professor in 1864; after which date the rest of his life was spent in connection with the University.

The long range of his life finds a parallel in the long range of his scientific activity; a couple of facts may suffice in illustration of its now distant beginning. As long ago as 1840, he prepared a memoir on elliptic functions, then called modular functions (it constitutes that portion of his now classical memoir "Theorie der Abelschen Functionen," which relates to elliptic functions): in 1840, Cayley was an undergraduate at Cambridge. Weierstrass's first paper on the higher Abelian transcendental functions was published in 1848; the contributions, which he then made to the theory, and the analytical method, which he then was perfecting, have been of significant import in the algebraical development of the theory of these functions. In 1848, Riemann was a student in Berlin; to the younger generation of mathematicians Riemann seems to belong to the past, for he died more than thirty years ago.

This is not the occasion to write of Weierstrass's work in detail, or to sketch the magnitude of his influence upon science and upon mathematicians. Its appreciation in England was marked by the Royal Society in 1881, when he was elected a foreign member of that body, and again in 1895, when he was awarded the Copley medal—the highest honour which the President and Council have the power to bestow in recognition of scientific worth. It would be idle to surmise what Weierstrass's precise place in the history of his subject may prove to be, and its consideration may fairly be left to the future: any contemporary estimate would make it high and honourable. He has been described as the parent of modern mathematical analysis; his years and his knowledge had made him a Nestor among mathematicians; and those who knew his writings, even though they may not have known the man, will learn of his death with a sense of personal regret.

A. R. F.

NOTES

M. G. DARBOUX, the distinguished professor of higher geometry in the University of Paris, has been elected a corresponding member of the Berlin Academy of Sciences.

THE fifth "James Forrest" lecture of the Institution of Civil Engineers will be delivered by Dr. G. Sims Woodhead on Thursday, March 18, on "Bacteriology."

A SPECIAL meeting of the Chemical Society is announced for Thursday, March 25, at eight o'clock, when Prof. Percy Frankland, F.R.S., will deliver the Pasteur Memorial lecture.

THE contributions so far sent by members of the General Committee of the British Section of the Pasteur International Memorial, amount to 425*l.* (10,625 francs). This sum has been forwarded to the Central Fund in Paris.

MR. EDGAR THURSTON, Superintendent of the Madras Museum, has just arrived in England on a year's leave of absence.

MR. W. HARCOURT-BATH, who contributes to the March number of *The Entomologist* a suggestive note on the causes of the decadence of the British Rhopalocera, is about to leave England upon an entomological expedition to the Himalayas.

WE regret to announce the deaths of Prof. Georges Ville, professor of botanical physics in the Paris Natural History Museum, and Geheimrath Wilhelm Döllen, formerly assistant in the Observatories of Dorpat and Pulkova, and the author of a number of important papers in geodesy and astronomy.

THE Council of the Society of Arts will proceed to consider the award of the Albert Medal for 1897 early in May next, and they, therefore, invite members of the Society to forward to the Secretary, on or before the 10th of April, the names of such men of high distinction as they may think worthy of this honour. The medal was struck to reward "distinguished merit for promoting Arts, Manufactures, or Commerce," and was last awarded to Prof. D. E. Hughes, F.R.S.

THE Victorian Era Exhibition, to be held this year at Earl's Court, London, S.W., will comprise scientific and economic sections. The object of the exhibition is to show the advances which have been made during the sixty years of the reign of Her Majesty the Queen. In the scientific section it is intended to devote particular attention to the discoveries and inventions made in the United Kingdom during the Victorian era, and their development and application to purposes of general public utility. The chairman of the sub-committee of this section is Major-General Sir John Donnelly, R.E., K.C.B., and the vice-chairman, Mr. W. H. Preece, C.B., F.R.S. There are fifteen other members of the committee, most of them being Fellows of the Royal Society, and all of them known in the scientific world.

THE Mathematical and Physical Section of the Royal Society of Naples announces that the mathematical prize of 1896 is unawarded, and the competition will be postponed till March 31, 1898. The theme for the prize is as follows:—To expound, discuss, and coordinate, possibly in a compendious form, all researches concerning the totality of prime numbers, introducing some noteworthy contribution to the laws according to which these numbers are distributed among integers The essays may be written in Italian, French, or Latin.

H.S.H. PRINCE ALBERT OF MONACO has just published, in the *Comptes rendus*, the usual summary of his work in the Atlantic and Mediterranean. The third season's cruise includes 82 soundings, with 19 sets of temperature observations; samples of air and water were collected and examined, the former in the open sea and at high altitudes on the Azores. The most interesting result obtained is the discovery of a new bank, christened the Princess Alice Bank, near the Azores, between 31° 28′ and 31° 41′ N. lat. and 37° 50′ and 38° W. long. This bank lies N.W. to S.E., bottom rock and volcanic sand, at a mean depth of 252 metres, and has a rich and abundant fauna. On June 4 to 6, between Monaco and Corsica, hundreds of swallows alighted on the vessel and showed themselves remarkably tame, making their way into the engine-room and stoke-hold, and feeding from the sailors' hands.

M. JULES RICHARD, zoologist on board the Prince of Monaco's vessel, describes in the *Comptes rendus* an apparatus devised by him with the view of ascertaining whether the amount of gases dissolved in sea water is independent of pressure at great depths, or not. A steel bottle filled with mercury, and ingeniously arranged to remain vertically inverted over a beaker, was allowed to slide down the sounding line till, at the required depth, a catch previously attached to the line actuated an arrangement for lowering the beaker slightly, allowing mercury to escape from the bottle and to be replaced by water. A messenger, sent down later, "set off" the reversing thermometer, and at the same time lowered the steel bottle again into the mercury of the beaker. On drawing the whole up, any gases not in solution must have been set free, either by change of temperature or of pressure. The result of two satisfactory experiments at depths of 1000 and 2700 metres is to confirm previous experience that the quantity of gas dissolved is independent of the pressure. M. Richard applies a similar mechanical arrangement to a modification of Giesbrecht's tow-net, which he describes in the *Bulletin de la Société Zoologique de France*. The tow-net is placed on the sounding-line *after* the latter has been lowered to the desired depth, and allowed to slide down closed, until a stop on the line arrests and opens it. Before hauling up, the mouth of the net is again closed by a messenger let down from the surface. In a series of notes, M. Richard contributes to the same publication observations on a *Limnicythera* of the lakes in the Bois de Boulogne, on the fresh-water fauna of the Azores, and on the fauna of some high lakes in the Caucasus, the last from collections by M. Kavraisky.

ABUNDANT stores of cleveite, alvite, monazite, and other rare minerals, have been found in a mine recently discovered at Ryfylke, Norway. A specimen of the cleveite has been sent to us, and it proves to be very rich in helium. Many investigators will be glad to know that the minerals can be purchased at a comparatively low price, particulars of which will be found in our advertisement columns.

FROM a careful study of James Glaisher's aerostatical observations, Signor F. Siacci has propounded two new formulæ representing the law of decrease of atmospheric temperature and aqueous vapour with the altitude. From these he has deduced a new barometric formula for the measurement of altitudes, as simple as Laplace's formula, and which, when tested on Monviso and Mount Etna, has given almost perfect results.

AN investigation of certain new series for the Gamma Function has been given by Herr G. Landsberg, of Heidelberg, who has discovered some remarkable generalisations of Stirling's and Kummer's series. The two new series, of which these are particular cases, are shown to be closely connected together, a result the more remarkable in view of the fact that Kummer's series is convergent for certain values of the variable, while Stirling's series is always semi-convergent, being ultimately divergent, though the convergent portion can be used for practical approximations. Herr Landsberg's paper is to be published by the Royal Academy of Belgium among their foreign memoirs.

THE brilliantly iridescent colours of the scales on the Brazilian diamond beetle (*Entimus imperialis*) have been examined by Dr. Garbasso, who finds that, unlike the corresponding colours in Lepidoptera, these are entirely due to interference, and are of the nature of colours of thin plates. With transmitted and reflected light the colours seen are complementary; moreover, the colours can be altered by subjecting the scale to pressure; again, on moistening and subsequently drying the scale, changes of colour are observed not unlike those produced in M. Lippmann's colour-photographs when the gelatine film has been moistened and allowed to dry. All these phenomena accord with the view that the scales consist of two layers separated by a thin interspace. Dr. Garbasso's paper is published in the *Memorie della R. Accademia delle Scienze di Torino*.

PROF. F. PLATEAU, of the University of Ghent, has for many years carried on a series of observations on the mode in which insects are attracted to flowers, the results of which are published in the *Bulletin* of the Royal Academy of Sciences of Belgium. His conclusions are not in accord with that of Darwin, that the bright colour of the corolla acts as a beacon to attract insects. He believes that they are attracted chiefly by some other sense than that of sight, probably that of smell. In the case of the dahlia (single) and other species of Compositæ, the removal of the conspicuous ray-florets had but little effect on the visits of insects; nor had the removal of the conspicuous part of the corolla in other flowers, as long as the nectary remained. On the other hand, the artificial placing of honey on otherwise scentless flowers resulted in their being immediately visited by numbers of insects. Where the same species varies in the colour of the flower, as between blue and white, or red and white, insects visit quite indifferently flowers of different colours belonging to the same species.

AN interesting paper by Prof. F. Omori, on the intensity and amplitude of the motion in the great Japanese earthquake of 1891, appears in the latest *Bollettino* (vol. ii. N. 6) of the Italian Seismological Society. At Osaka, distant 140 km. from the place where the shock was most severe, the maximum horizontal displacement (or double amplitude) was 30 mm., and the maximum acceleration, which measures the intensity, 600 mm. per sec. per. sec. At Tōkiō, distant 270 km., the displacement was about 45 mm., and the maximum acceleration 230 mm. per sec. per sec. These values were obtained from seismographic records. Nearer the epicentre, the maximum acceleration can only be determined by observations on the overturning or fracturing of various bodies. At two places in the province of Owari, it exceeded 4300 mm. per sec. per sec.; while at Nagoya, in the same province, it was found to be 2600 mm. per second, and the greatest displacement 220 mm.

IN the January number of *Natur und Offenbarung* (Münster), Dr. J. W. van Bebber gives an interesting account of the methods employed and the success attained in the telegraphic weather service of the Deutsche Seewarte at Hamburg, and traces the history of this branch of meteorological science since the invention of the optical telegraph in 1793. The question of the actual results attained is not so easy to decide as might at first sight appear, owing to the various methods employed in checking them, and the different purposes for which the forecasts are used. Seamen are mostly concerned with the direction and force of wind, while agriculturists are chiefly interested with temperature, and fine or wet weather. In the present state of the science, the former conditions are much easier to predict than the latter. So far as storm warnings are concerned, the author has investigated the cases in which shipping casualties have occurred on the German coasts for a considerable number of years, and finds that in nearly all cases successful warnings were issued. The methods employed are nearly similar to those followed in this country; telegrams are received at various hours showing, according to the international code, the actual conditions, and the changes since the previous reports. In the morning five weather charts are simultaneously prepared, showing respectively the barometric pressure, wind direction and force, state of the sky, temperature, and rainfall, &c. In the afternoon two charts are drawn, showing the air-pressure, temperature, and the variations since the morning, and during the unsettled season (September to April) further charts are constructed, showing the conditions in the evening.

THE current number of the *Revue de l'Université de Bruxelles* contains an interesting memoir by Dr. Funck, entitled "Les vaccinations contre le choléra aux Indes." It will be remembered that the first attempts at anti-cholera vaccination originated with and were carried out by a Spanish medical man, Dr. Ferran, some twelve years ago, and we can but admire the splendid audacity which in those early days led him to practise inoculations with living cholera bacilli. His vaccine consisted of eight drops of a cholera culture mixed with bile, and the misfortunes which followed his inoculations were, probably, largely attributable to his cholera cultures not being pure. That considerable faith was in the first instance placed in Ferran's process, is shown by the fact that some 25,000 persons underwent the treatment. Haffkine's vaccinations against cholera are a direct outcome of the pioneering work published by Ferran on this subject in 1885. In the inoculations which have proved so successful in India, Haffkine employs first, attenuated cholera bacilli, and then, a few days later, virulent cholera cultures; but recently Kolle has obtained equally good results by using dead cholera bacilli, which have been destroyed either by heat or chloroform. In the latter process rather larger doses have to be employed to produce the same effect. The blood of persons vaccinated against cholera has been tested as to its protective potency, and it has been found to be two hundred times more active against cholera infection than that of a non-vaccinated individual. That improved sanitation and enlightened hygienic measures are capable of combating cholera to a most important extent, is shown by the fact that, since the year 1892, whilst in Russia 800,000 individuals have fallen victims to cholera; in Germany, including the Hamburg cholera epidemic, only 9000 cholera deaths have been recorded.

A DESCRIPTIVE list of all published observations of the Aurora Australis is given by Dr. Wilhelm Boller in Gerland's "Beiträge zur Geophysik" (vol. iii.). From this catalogue it appears that the greatest number of observations were made in March and October, and the least in June and November. As with the Aurora Borealis, the frequency of the phenomena seems to vary in consonance with the eleven-year period of solar activity. The line which embraces all the observations is a circle around the south magnetic pole, this result being similar to that obtained by Nordenskiöld from the observations of the Aurora Borealis. Dr. Boller intends to amplify and continue his catalogue, and for that purpose he will be glad to know of any records overlooked by him, or of any observations which may be made in the future. Letters will find him at the Geographical Seminary of the University of Strasburg.

EVIDENCE of the former extension of glacial action on the west coast of Greenland, and in Labrador and Baffin Land, is given by Mr. George H. Barton in the *American Geologist* (December 1896), an excerpt from which has just been sent to us. Mr. Barton went to northern Greenland with the sixth Peary expedition in the summer of last year, and he proposes to continue his observations during the coming summer, when Lieut. Peary will take another expedition to Greenland for the purpose of obtaining the large meteorite which could not be shipped last year. The coast of Greenland offers exceptional facilities for the study of glacial phenomena. It is hoped, therefore, that, as Cornell University and the Massachusetts Institute of Technology sent parties with the Peary expedition last year, other universities, colleges, and scientific organisations will send parties to accompany the forthcoming expedition.

AN interesting contribution to the question "How do igneous rocks intrude?" has been made by Prof. I. C. Russell, in two papers to the *Journal of Geology*, and one to the *Popular Science Monthly* (December 1896). Besides bringing together a number of suggestions already made, he introduces some new ideas based on his study of the Black Hills of Dakota. In that region a number of structures are found (of which striking photographs are given), resembling the famous laccolites of the Henry Mountains, but, in part, differing from them in the absence of any lateral extension. These Prof. Russell calls *plutonic plugs*. A study of these leads him to the suggestion that the whole of the Black Hills uplift, and other mountain uplifts in which direct elevation and stretching take the place of compression and crumpling, may be due to enormous laccolite-like intrusions of molten rock at a great depth. Such an intrusion he terms a *subtuberant mountain*, and suggests that crystalline areas, commonly said to show "regional metamorphism," may be such subtuberant mountains laid bare.

OUR congratulations to the Leicester Literary and Philosophical Society. Stimulated into action by a paper on the disappearances of certain species of insects, by Mr. Frank Bouskell, a Committee was formed to formulate regulations for the protection of local species. As a result of their deliberations, a list of insects has been drawn up, and the number of each allowed to be taken by members of the Society in one season has been specified. When a collector now sees *Leucophasia sinapsis* (the Wood White butterfly), he must hold his hand and crush his sporting instinct, for none of this insect are to be taken. Of *Macroglossa fuciformis* only one specimen must be taken by each member in a single season, and only one specimen of *Sesia apiformis*. The penalty for breaking these regulations are drastic. If a member of the Society, the transgressor is liable to be expelled by a bare majority of the members present at any meeting, and if a member of any other Society, the transgression will be reported to that Society. Landowners will also be asked to refuse to permit offenders to pass through their grounds. The over-zealous collector will, indeed, be ostracised, and will find that no one will buy from him, exchange with him, or have anything to do with him entomologically. There may be a difficulty in carrying out the regulations, and one result will probably be that collectors will prefer to go out alone in the future. But it is hoped that entomologists will remember that they are not supposed merely to fulfil the functions of a fly-paper, but also to work for the advancement of their science.

LECTURERS upon geography will be glad to know that lantern slides of the illustrations in Dr. Nansen's "Farthest North" are now published by Messrs. Newton and Co., who made the slides which Dr. Nansen uses at his own lectures.

AN elaborate descriptive catalogue of chemical apparatus, containing more than five hundred pages, has been issued by Messrs. A. Gallenkamp and Co. The list contains quotations for apparatus and accessories used in every branch of chemistry, and the prices are given both for Germany and the United Kingdom.

The *Rendiconti del R. Istituto Lombardo* (xxx. iii.) contains papers, by G. Melzi, "On Certain Rocks from the Island of Ceylon," and an account, by Prof. C. Somigliana, of some determinations of the specific heat of sea and lake water, undertaken by the late Prof. Adolfo Bartoli, of Pavia, shortly before his death, and forming his last contributions to science.

THE March number of the *Geographical Journal* contains a fine portrait of Dr. Nansen, reproduced by the Swan Electric Engraving Company, and an illustration of the special medal presented to him by the Royal Geographical Society. The address delivered in the Albert Hall, on February 8, is not printed in the *Journal*, because Dr. Nansen is delivering it in

different parts of the United Kingdom during the present month.

TWO parts recently issued complete the ninth volume of that useful publication, *The Essex Naturalist*. A more than local interest attaches to the reports on the borings for coal at Stutton and Weeley, on the latter of which more details are promised in the next number. Both borings have been unsuccessful in their primary object, high-dipping unfossiliferous rocks, of at least Lower Carboniferous age, coming immediately under the Gault in both cases. Among the numerous papers and notes on Essex matters, we note a contour-shaded map of South Essex, prepared by Mr. T. V. Holmes, which may be regarded as an example of how accurate small-scale maps can be produced: it is reduced by photography from a shaded six-inch map.

THE well-known work on "Metals; their properties and treatment," published in Messrs. Longmans' series of Text-Books of Science, has been considerably enlarged by Prof. A. K. Huntington and Mr. W. G. McMillan. The work originally appeared in 1872, and occupied 312 pages; but, in order to include the great developments which have taken place in the practice of metallurgy in recent years, it has had to be extended to 562 pages, and even now Prof. Huntington regrets that he has not been able to deal with each branch of the subject fully enough to satisfy himself. Notwithstanding this statute of limitations, the new edition of "Metals" has been brought up to date so satisfactorily that it will certainly meet with a hearty reception. The object of the book is to "make clear the principles which have guided the evolution of the metallurgical arts and industries, avoiding multiplicity of detail, which tends to obscure main issues." The present edition of the book shows that this object has been borne in mind throughout, the result being a readable and instructive volume.

THE report drawn up by Prof. W. A. Herdman and Mr. Andrew Scott, on the investigations carried on, in 1896, in connection with the Lancashire Sea-Fisheries Laboratory at University College, Liverpool, contains many noteworthy matters. Particular attention is given to the description of work on oysters and their possible connection with disease in man. Prof. Herdman urges moderation on the part of those sanitary reformers who expect the conditions in which oysters are kept to be perfect. "After all," he says, "we do not want—even if we could get it—an aseptic oyster. The rest of our food—our milk, our bread and cheese, our ham sandwiches, and so on—are teeming with germs, most of them harmless so far as we know; but some of them may be just as bad as any that can be in shellfish. If we were to insist on breathing filtered air, and eating nothing but sterile food, washed down with antiseptic drinks, we should probably die of starvation, or something worse, if we did not go mad first with the constant anxiety." It is held that the object should be to get our oyster-beds as healthy as possible, but not to insist upon conditions which will make it impossible to rear any oysters at all. As the result of work carried out with Prof. Boyce, Prof. Herdman recommends that all grounds upon which shellfish are grown or bedded should be inspected, so as to ensure their practical freedom from sewage, and also that oysters should be kept alive for a short time in running water; for experiments show that the living animal soon gets rid of any disease germs with which it may be infected, if it is kept in clean water. A catalogue of the Fisheries Collection in the Zoological Department of the University College, Liverpool, is appended to Prof. Herdman's report.

TWO papers, extracted from the thirteenth annual report of the Bureau of Ethnology, have come to us from Mr. Cosmos Mindeleff. One is on the "Casa Grande Ruin," situated near Gila River, in Southern Arizona, and the best-known specimen of aboriginal architecture in the United States. The accurate plans and careful descriptions contained in this paper should be very valuable to students of American antiquities. It is concluded that the Casa Grande was undoubtedly built and occupied by a branch of the Pueblo race, or by an allied people. These people were probably the ancestors of the present Pima Indians, now found in the vicinity, and known to be a pueblo-building tribe. The subject of Mr. Cosmos Mindeleff's second memoir is "Aboriginal Remains in Verde Valley, Arizona." It is concluded that these ruins represent a comparatively late period in the history of the Pueblo tribes. There is no essential difference, other than those due to immediate environment, between the architecture of the lower Verde region and that of the more primitive types—Tusayan, for example—found in other regions. The Verde architecture is, however, of a more purely aboriginal type than that of any modern pueblo, and the absence of introduced or foreign ideas is its chief characteristic. The remains suggest that cavate lodges and cliff-dwellings are simple varieties of the same phase of life, and that life was an agricultural one. Mr. Mindeleff's paper is a very valuable contribution to the knowledge concerning the interesting archæological remains of the Rio Verde valley, and their position among types of house structure.

THE fourth Annual Report of the Shanghai Meteorological Society contains an interesting essay on the variations of the atmospheric pressure over Siberia and Eastern Asia during the months of January and February 1890, by the Rev. S. Chevalier, S.J., Director of the Zi-ka-wei Observatory, and President of the Society. The investigation was undertaken to elucidate some of the more doubtful points relating to winter storms in the Eastern seas, and for this purpose synoptic charts have been drawn twice daily for the period in question, showing the distribution of barometric pressure over Siberia and Eastern Asia, based chiefly upon the reports issued by the Russian, Chinese and Japanese services. The conclusions arrived at show that while some of the cyclonic storms may make a tour of the globe, most of them experience great difficulty in crossing Western Siberia, and are generally deflected towards the North Pole by the high pressure prevailing over Central Siberia. The depressions over Siberia, though far distant from the coasts of China, affect, at least indirectly, the weather of those parts; and the author finds that the winter storms of China are very generally preceded by the passage of extra-tropical cyclones. The violence of the gales not only depends upon the depth of the disturbance, but also upon the character of the high-pressure areas in the rear of the depression.

THE additions to the Zoological Society's Gardens during the past week include a Yellow-bellied Liothrix (*Liothrix luteus*) from India, presented by Madame Caté; a Viperine Snake (*Tropidonotus viperinus*), Europe, presented by Mr. J. H. M. Furse; eleven Scorpion Mud Terrapins (*Cinosternon scorpoides*) from North Brazil, presented by Dr. Émil A. Goeldi; a Yellow-cheeked Amazon (*Chrysotis autumnalis*) from Honduras, presented by Mrs. Annie Kattengell; two Chipping Squirrels (*Tamias striatus*) from North America, deposited; a Common Otter (*Lutra vulgaris*) from Berkshire, a Salle's Amazon (*Chrysotis ventralis*) from St. Domingo, purchased; two Egyptian Jerboas (*Dipus ægyptius*), nine Egyptian Cobras (*Naia haje*), two Cerastes Vipers (*Cerastes cornutus*), twelve Egyptian Eryx (*Eryx jaculus*), a Clifford's Snake (*Zamenis diadema*), two Hissing Sand Snakes (*Psammophis sibilans*), two —— Snakes (*Zamensis florulentus*) from Egypt, received in exchange.

OUR ASTRONOMICAL COLUMN.

DRAWINGS OF MERCURY.—Mr. Percival Lowell, writing (*Astr. Nach.*, No. 3407) of the planet Mercury, says that the markings of the planet are distinct and dark. They are generally of the nature of lines. Both poles, he says, are shaded, and there is a conspicuous dark band cutting off the southern one from the rest of the planet. This band is stated to be continuous for several degrees of longitude, and may possibly girdle the zone completely. The period of rotation of the planet was found to be synchronous with the orbital revolution, thus endorsing Schiaparelli's previously determined period of eighty-eight days. Even from the drawings, several of which are reproduced, a slow period of rotation seems the more probable, while observations made since they were completed confirm this still more.

PROMINENCE PHOTOGRAPHY.—During the last twelve months many attempts have been made to obtain impressions on a photographic plate, showing various solar phenomena, and all of them have had for their basis the well-known action of electrical radiation on a sensitive film. The method consists in wrapping a plate in some opaque material, velvet, tinfoil, paper, &c., and then exposing it to the sun, using either the general diffused light, or the image formed by an object-glass or in a pin-hole camera. In several cases results have been obtained more or less consistent, but in general the impressions have been dissimilar at each trial, thus suggesting accidental causes for the effect. In the *Photogram* for July 1896, Mr. D. Packer gave several photographs of impressions he had obtained on plates exposed in this way, which were supposed to show the details of the solar corona. Results exactly similar to those given have been obtained by the writer, but in every case the effect could be traced to imperfections in the wrapping of the plate, and the consequent spreading of the light thus admitted direct to the film.

Now in the current *Comptes rendus* (p. 459), M. P. de Heen describes the appearance he gets on exposing a covered plate at the focus of a small object-glass. He finds that a ring is produced on the plate, corresponding to the solar atmosphere in size, and thinks that the chromosphere is the seat of electric radiations, while the photosphere is simply the source of luminous radiation, thus suggesting that, if true, this may furnish a method of examining the spots and prominences.

OXYGEN IN THE SUN.—Some time ago (NATURE, vol. lv. p. 303) we pointed out in this column that Herren Runge and Paschen had reason to believe that the three lines of oxygen—7772·26, 7774·30, and 7775·97—in the solar spectrum were probably not atmospheric, and we further mentioned that a crucial test could be made by examining the solar spectrum for motion in the line of sight. Mr. Lewis Jewell has taken up this problem, and contributes the result of his inquiry to the *Astrophysical Journal* (February 1897, p. 99). He found that using a grating, 15,000 lines to the inch, the spectrum was so exceedingly weak to the eye when the slit of the spectroscope was placed near the edge of the sun's disc, that no satisfactory observations of the three lines mentioned above could be made.

Mr. Jewell then turned his attention to investigating whether a high or low sun caused any appreciable difference in intensity of these lines. In this he was more fortunate, and is now able to state that his observations "prove conclusively that the three lines supposed to be due to oxygen in the sun are produced by water vapour in the earth's atmosphere."

THE TOTAL SOLAR ECLIPSE OF AUGUST 8, 1896.—In the January number of the *Bulletin* of the St. Petersburg Imperial Academy of Sciences (5th series, vol. vi. No. 1) appear three accounts of the observations made at Novaya Zemlya. The first is the report of Prof. O. Backlund, whose station was situated at Malya Karmakouly, and whose programme consisted in observing the contacts and sketching the corona. The weather seemed to have been all that could be desired, and all four contacts were obtained. The second report is made by M. S. Kostinsky and A. Hansky, who observed from the same station. This is accompanied by some excellent reproductions taken direct from the enlarged negatives, showing an amount of detail in the streamers that is seldom obtained. One photograph was taken about third contact, and shows that interesting phenomenon known as "Baily's beads," which interferes so much with the estimation of the exact observed time of contact. There is also a plate showing the corona and a large region of the sky around it: conspicuous on this are Jupiter and several stars. An excellent drawing of the details, as gathered from a minute examination of all the photographs taken, is further added. Lieut. Bouchteeff, who was carrying on some hydrographic operations at Novaya Zemlya, observed the eclipse from the Bay of Belougia Gouba. He noted the times of all four contacts, and made a rough sketch of the corona, which are all given in his report published in this *Bulletin*.

THE CHEMISTRY OF THE STARS.—The rapid strides that have been made in the development of spectrum analysis since the time of Wollaston, and the important step taken by Prof. Pickering in the adoption of the prismatic-camera form of instrument, have led many to investigate the spectra of the stars in our universe. Such a survey, although slow to accomplish, is of great importance, since we are able to pass at a bound from terrestrial temperatures, and observe the behaviour of our elements at temperatures far beyond our ken. The chemist is thus left far behind, and is restricted to a very limited range of temperature, while the astronomer has at his disposal temperatures the magnitude of which cannot be even conceived. That the celestial bodies about us vary enormously in their degrees of temperature is now admitted by every one, and some idea of the different kinds of spectra emitted by these bodies may be gathered from Mr. Fowler's interesting article in *Knowledge* (March), which deals in the main with the important work that is being carried on at Kensington under the direction of Mr. Norman Lockyer. That the stars are now being successfully classified in a closed curve—*i.e.* some are increasing and some decreasing their temperatures—is only one of many important advances of the last few years. The recent discovery of the new form of hydrogen, by Prof. Pickering, is another rundle in the ladder of temperature, which seems to indicate that even in those stars within our sphere of the cosmos we may not have examples of the *highest* attainable temperature.

ON ELECTRIC EQUILIBRIUM BETWEEN URANIUM AND AN INSULATED METAL IN ITS NEIGHBOURHOOD.[1]

THE wonderful fact that uranium held in the neighbourhood of an electrified body diselectrifies it, was first discovered by H. Becquerel. Through the kindness of M. Moissan we have had a disc of this metal, about five centimetres in diameter and a half-centimetre in thickness, placed at our disposal.

We made a few preliminary observations on its diselectrifying property. We observed first the rate of discharge when a body was charged to different potentials. We found that the quantity lost per half-minute was very far from increasing in simple proportion to the voltage, from 5 volts up to 2100 volts; the electrified body being at a distance of about 2 cms. from the uranium discs. [*Added March* 9.—We have to-day seen Prof. Becquerel's paper in *Comptes rendus* for March 1. It gives us great pleasure to find that the results we have obtained on discharge by uranium at different voltages have been obtained in another way by the discoverer of the effect. A very interesting account will be found in the paper above cited, which was read to the French Academy of Sciences on the same evening, curiously enough, as ours was read before the Royal Society of Edinburgh.]

These first experiments were made with no screen placed between the uranium and the charged body. We afterwards found that there was also a discharging effect, though much slower, when the uranium was wrapped in tinfoil. The effect was still observable when an aluminium screen was placed between the uranium, wrapped in tinfoil, and the charged body.

To make experiments on the electric equilibrium between uranium and a metal in its neighbourhood, we connected an insulated horizontal metal disc to the insulated pair of quadrants of an electrometer. We placed the uranium opposite this disc, and connected it and the other pair of quadrants of the electrometer to sheaths. The surface of the uranium was parallel to that of the insulated metal disc, and at a distance of about 1 cm. from it. It was so arranged as to allow of its easy removal.

With a polished aluminium disc as the insulated metal, and with a similar piece of aluminium placed opposite it, in place of the uranium, no deviation from the metallic zero was found when the pairs of quadrants were insulated from one another. With

[1] By Lord Kelvin, Dr. J. Carruthers Beattie, Dr. M. Smoluchowski de Smolan. Read before the Royal Society of Edinburgh, March 1.

the uranium opposite the insulated polished aluminium, a deviation of −84 sc. divs. from the metallic zero was found in about half a minute. After that the electrometer reading remained steady at this point, which we may call the uranium rays-zero for the two metals separated by air which was traversed by uranium rays. If, instead of having the uranium opposite to the aluminium, with only air between them, the uranium was wrapped in a piece taken from the same aluminium sheet, and then placed opposite to the insulated polished aluminium disc, no deviation was produced. Thus in this case the rays-zero agreed with the metallic zero.

With polished copper as the insulated metal, and the uranium separated only by air from this copper, there was a deviation of about +10 sc. divs. With the uranium wrapped in thin sheet aluminium and placed in position opposite the insulated copper disc, a deviation from the metallic zero of + 43 sc. divs. was produced in two minutes, and at the end of that time a steady state had not been reached.

With oxidised copper as the insulated metal, opposed to the uranium with only air between them, a deviation from the metallic zero of about +25 sc. divs. was produced.

When the uranium, instead of being placed at a distance of one centimetre from the insulated metal disc, was placed at a distance of two or three millimetres, the deviation from the metallic zero was the same.

These experiments show that two polished metallic surfaces connected to the sheath and the insulated electrode of an electrometer, when the air between them is influenced by the uranium rays, give a deflection from the metallic zero, the same in direction, and of about the same amount, as when the two metals are connected by a drop of water.

THE EXTRACTION OF GOLD BY CHEMICAL METHODS.

EXCLUDING mechanical, smelting, and amalgamation processes, the methods of extracting gold from its ores may conveniently be grouped together under the heading of wet or chemical methods. In these, the gold is dissolved by some suitable solvent, and is then separated from the unaltered ore by washing, and recovered by precipitation. The processes owe their origin to the rapid advance in the science of chemistry which has been made during the present century, and, although they are now of vast importance, and give results which would astonish our grandfathers, it is, perhaps, somewhat surprising that chemistry has not done more for the gold-mining industry. At the present day, the wet methods produce little more than a tenth of the total output of gold, while mechanical improvements in the old processes, made during the last half-century, are probably answerable for four or five times as much.

Gold exists in nature practically only in one form, the metallic state, and the differences in treatment of the ores are necessitated by the variations in the physical condition of the metal, and by changes in the other constituents of the rock. Where the particles of gold are large enough to be seen by unassisted vision, they can usually be collected by means of mercury, and, on the other hand, are not dissolved in a reasonable time by any of the solvents of gold yet applied in practice. In these cases, therefore, chemical methods are not advantageous. Nevertheless, it usually happens that some, if not all, of the gold in an ore is in an extremely fine state of division. It has recently been shown by Edman that a great proportion of the gold in American ores consists of particles less than $\frac{1}{100000}$ inch in diameter, and that some of these are less than $\frac{1}{1250000}$ inch. Sometimes, gold in an ore is not visible even under the microscope, though readily detected by chemical means. Metal in such a condition is far more readily dissolved by a mobile liquid than by a viscous one like mercury, which does not wet the grains of sand between which the gold is hidden. Moreover, mercury may be prevented from doing its work by the presence of substances on which it exerts chemical action, such as the sulphides of antimony, or arsenic, or which protect the gold from its action by coating the particles with insoluble films.

From such causes as these, it has long been recognised that the treatment of gold ores by mercury is very imperfect in a great many cases. The method is, speaking generally, unsatisfactory in extracting gold contained in pyrites or other sulphides, and it is in the treatment of these substances that the chlorination process, now nearly fifty years old, has its main value.

Chlorine is a somewhat slow solvent for gold, but the time occupied by it in dissolving the fine flakes existing in pyrites is not excessive. Unfortunately, chlorine has a strongly preferential action on sulphides, and, to avoid the enormous waste of the gas which is entailed in the oxidation of a small percentage of these substances, it is necessary to precede chlorination by careful and complete roasting. Even in the rare cases, such as that of the Mount Morgan ore, in which the use of chlorine on completely oxidised ores is found to be desirable, the preliminary roasting is not omitted, as the percolation of liquids through the roasted mass is far easier than through the raw ore.

After roasting, there is little difficulty in the process. Oxides of the metals, except the alkaline earths, are very slowly attacked by chlorine; and when the alkaline earths are present salt is added in the roasting furnace. Here one of the sources of loss in the process is encountered, chloride of gold being formed and volatilised at all temperatures above 200°, when common salt is mixed with the ore. In long-bedded furnaces, however, this loss is reduced to a minimum; chloride of gold is prevented from formation by the presence of large quantities of unoxidised pyrites, and when formed, in the oxidised product in the hottest part of the furnace, it is in great part decomposed and re-absorbed during its passage over the bed of comparatively cool ore, which has just been charged into the furnace.

It was formerly the universal practice to apply the chlorine to the slightly-damped roasted ore in the form of gas, and this method has never been entirely abandoned. Subsequently, after Dr. Mears had discovered that compressed chlorine was more rapid in its action than the same agent under ordinary atmospheric pressure, strong aqueous solutions were used, the ore being agitated with the solvent in revolving barrels. This practice is still adhered to in several works in the United States. Elsewhere, however, it has been completely set aside. For example, at Mount Morgan, in Queensland, the largest chlorination mill in the world, stationary vats have been reverted to, aqueous solutions of chlorine being, however, still used. At this mill about 1,500 tons of ore are treated every week at a cost of about 18*s.* per ton, or little more than one-sixth of the value of the yield in gold.

After the ore has been treated with chlorine for a period varying in different mills from an hour to one or two days, the liquid is filtered off and the gold precipitated by ferrous sulphate, sulphuretted hydrogen, or charcoal. As regards the relative advantages of these methods, it may be noted that charcoal only acts well with boiling solutions, and that sulphuretted hydrogen is now recommended by its advocates even when copper is present in the ore, Rothwell having recently pointed out that in acid solutions there is partial precipitation, all the gold being removed from solution before the copper begins to come down.

The chlorination process, though perhaps unrivalled in the percentage of extraction which can usually be attained, labours under two serious disadvantages. Roasting the ore is often so expensive as to be impracticable, and the silver is, in any case, all lost. Both of these disadvantages are avoided by the use of the cyanide process. This was introduced by MacArthur and the Forrests after prolonged researches, having for their object the discovery of some chemical process which would not require a preliminary roasting of the ore.

The action of cyanide solutions on the precious metals had long been known. Elsner had stated, in 1846, that the presence of air was necessary for the dissolution of gold or silver by potassium cyanide, and, subsequently, it was suggested that the action was represented by the equation

$$4Au + 8KCy + O_2 + 2H_2O = 4KAuCy_2 + 4KHO.$$

This equation has recently been established by Maclaurin (*Jour. Chem. Soc.* vol. lxiii. (1893) p. 724; vol. lxvii. (1895) p. 199), who also showed that the dissolution of gold and silver becomes slower in proportion as free oxygen is more and more carefully excluded from the system. Thus, when a plate of gold was treated with a solution containing 1 per cent. of cyanide of potassium in a stoppered bottle filled with oxygen, the loss of weight was 0·24 gramme in 96 hours; in a shallow vessel exposed to the air, the loss was 0·00835 gramme in 24 hours, and in a flask, freed from air as completely as possible, the loss was only 0·0002 gramme in the same time. In addition, Maclaurin prepared the curves of solubility of gold and silver in cyanide solutions, and showed that the maximum rate of dissolution of both metals is reached at 0·25 per cent. of KCy, and

diminishes slowly as the concentration is increased, and rapidly if it is decreased.

These results are in perfect accord with the experience gained in practice on a large scale. Before Maclaurin's papers were published, the favourite stock solution in South Africa had for some time been one containing from 0·25 to 0·30 per cent. of cyanide, although weaker solutions are also used with excellent effect. Moreover, the difficulties introduced by a lack of free oxygen in the ore have long been severely felt. In particular, when concentrates containing much pyrites are treated, the absorption of oxygen by the sulphides is so rapid that the dissolution of gold is soon checked and becomes extremely slow. Thus, while gold-leaf floating on cyanide solutions is dissolved in a few minutes, and, if submerged, in a few hours, the films of gold in pyrites, which are probably similar in thickness to gold-leaf, often take two or three weeks in going into solution.

This is so far from satisfactory that many efforts have been made to increase the speed of action of cyanide in some way. An artificial supply of oxygen, or air forced through the charge of ore and solution, was found to shorten the time required but to increase the waste of cyanide, and similar results follow from the use of various oxidising agents, such as manganese dioxide, hydrogen peroxide, and bleaching powder.

Greater interest attaches to the proposal made by Sulman and Teed to add bromide of cyanogen to ordinary cyanide solutions (Trans. of the *Inst. of Mining and Metallurgy*, vol. iii. (1895), p. 202). They put forward the equation

$$CyBr + 3KCy + 2Au = 2KAuCy_2 + KBr$$

as expressing the action which takes place, but no direct proof has yet been afforded of the validity of this equation. These experimenters are, however, convinced that oxygen plays no part in the action, and, consequently, that except for the fact that the edges only of the films of gold in pyrites are presented for attack, solution of the gold in concentrates is as rapid as that in quartzose ores. This view is borne out by a number of trials on half-ton lots of ore, although no results of actual working have yet been published. Even when there is full access of air, however, as in the case of gold-leaf floating on the solution, the addition of cyanogen bromide greatly increases the rate of action of potassium cyanide, and if air and bromine are together passed through a solution of cyanide, the rate is increased about 100 times.

Slowness of action in dissolving gold is of more importance than may at first sight appear, for it must be remembered that alkaline cyanides attack many of the constituents of gold ores at varying rates, and, therefore, that the longer the solution is left in contact with the ore, the greater will be the decomposition of the cyanide, and, consequently, the greater the total cost of the process. Decomposing pyrites (especially if sulphide of copper is present) are, when not in perfect contact with gold, particularly active in destroying cyanide, and, in order to partially prevent their effect, it is customary to neutralise ores which have been rendered acid by the formation of sulphates by "weathering." The neutralisation is effected by the addition of a solution of caustic soda, or, more usually, of lime to the ore before it is treated with cyanide. The destruction of cyanide, however, still goes on to a limited extent in such cases, and treatment is rendered practicable only by the preferential or more rapid action of very dilute solutions of cyanide on gold as compared with their action on the sulphides.

The relative rates of action of cyanogen bromide on gold, and on the various sulphides and oxides met with in ores, remain undetermined, or at any rate unpublished, and until more light is thrown on these, either by laboratory experiments or by practical work on a large scale, it is impossible to judge what may be the future of the process. From some experiments, already made, it would appear that cyanogen bromide suffers considerable decomposition when placed in contact with some of the minerals met with in gold ores, and so it may happen that in many cases the haloid compound will be destroyed before it has time to get fairly to work in dissolving the gold.

The gold is recovered from solution either by its precipitation and replacement in solution by a metal positive to it in cyanide solutions, or by electro-deposition. The only metal largely used in practice is zinc, the action being one of direct replacement, expressed by the equation

$$2KAuCy_2 + Zn = 2Au + K_2ZnCy_4.$$

It has been found necessary to use the zinc in a fine state of division, and the filaments, prepared by turning zinc in a lathe, are certainly more efficient than other forms. The shavings are no more than 0·1 m.m. in thickness, and 0·5 m.m. in width. When packed in spongy form they weigh about six or seven lbs. per cubic foot and can be ignited by a lucifer match, burning readily to zinc oxide. They must be freshly turned, as in practice the cyanide solutions are too dilute to clean dirty surfaces by dissolving hydrates or carbonates of zinc.

The action of the zinc is undoubtedly aided by the presence of lead, which exists as an impurity in commercial zinc to the extent of about 1 per cent., and by the iron gratings on which the filaments rest. Galvanic couples are thus formed, which assist in starting the action. Nevertheless, precipitation of the gold is at first slow, especially in very dilute solutions, and it is only after some gold has been thrown down, and the gold-zinc couple formed, that the action becomes fairly vigorous. When the amount of gold in solution has fallen to about 0·0003 per cent., or from 1½ to 2 dwts. per ton of liquid, the action again becomes slow, and this amount is left unprecipitated in practice, but, as the solutions are used again on fresh charges of ore, no loss of gold occurs.

The black slimy deposit of gold, or alloy of gold and zinc thus formed, is washed and sieved off from the undecomposed zinc as far as possible, and is dried, roasted, and melted down with borax, carbonate of soda, and other fluxes, with or without a previous treatment with dilute sulphuric acid. The bullion thus obtained is very base, containing about 700 of gold per 1000, and variable quantities of zinc, lead, copper, and other metals. It is subject to the disadvantage that assay pieces, taken in the ordinary way, frequently differ in composition from the ingot taken as a whole.

The recovery of the gold from cyanide solutions by electro-deposition is the basis of the Siemens-Halske process. In this process the kathodes are of iron, and the anodes of lead foil. A very large surface is given to the electrodes, 12,000 square feet of surface of lead being exposed in the treatment of 70 tons of solution per day at the Worcester Mine in the Transvaal. At stated intervals, the lead anodes, containing from 2 to 12 per cent. of gold, are removed, melted down, and cupelled. The bullion produced is very fine, but the cost of precipitation appears to be greater than that by the zinc process, the main items being the lead and iron consumed. The current needed is only about 0·06 ampere per square foot, the power required being about 5 h.p. in the treatment of 70 tons of solution per day. The process makes but slow progress, only a small proportion of the gold produced by cyanide on the Rand being obtained in this way. T. K. ROSE.

AGRICULTURAL TEACHING AT OXFORD.[1]

THE present Professor of Rural Economy at Oxford has made use of the opportunity, afforded by the occurrence of the centenary of the foundation of his professorship, to discuss the general question of agricultural teaching in our Universities. After an interesting description of the life and work of Sibthorp, formerly Professor of Botany at Oxford, who literally gave up his life for the study of natural history on the shores of Greece, Prof. Warington proceeds, in the first place, to consider the important developments, both in the subject and in the means of teaching, which have taken place during the past century. He says:—

"The point on which I want to fix attention is the wholly different position in which agriculture stands at the present day from that which it held a hundred years ago. A hundred years ago agriculture was an art, having few points of contact with natural science. At the present time, both the materials and the operations of agriculture have been so far examined and elucidated by patient scientific investigation, that we may now fearlessly give the title of 'Agricultural Science' to the edifice of true theory which has been constructed. We need not shrink from making this claim because the theoretical edifice is still incomplete, for this incompleteness of theory is the normal condition of the natural sciences; what we assert is, that the whole field of agriculture is now occupied by the

1 "Agricultural Science: its place in a University Education." A lecture delivered before the University of Oxford, on November 5, 1896, on the occasion of the centenary of the foundation by Dr. John Sibthorp of the chair of Rural Economy, by Robert Warington, M.A., F.R.S., Sibthorpian Professor of Rural Economy. (London: Henry Frowde, 1896.)

scientific investigator, and that it is only a question of time when the problems still awaiting solution will cease to puzzle us."

This important change in the character of the subject is made the foundation of a claim for its fuller recognition by the University.

"In considering what should be the place of agriculture in University teaching, it is of primary importance that we should grasp the fact of the existence of this great body of agricultural science which has grown up during the last century. If agriculture is still merely an art, it has no proper place in University teaching, and those who wish to learn it must resort to some technical school for the purpose. If, on the other hand, agriculture is now as much a department of science as geology or medicine, it has an undoubted claim to be recognised, and its claim becomes urgent when we consider the vast importance of the subject."

The most important steps which have been taken in the development of agricultural teaching are then noticed, especial emphasis being laid on the great extension of such teaching during the last ten years, chiefly through the exertions of the County Councils and the Board of Agriculture. Not only have the means of instruction been greatly increased, there has also been a remarkable growth of opinion among the higher class of agriculturists as to the value of a thoroughly scientific training in the department of agriculture. Thus, in February 1893, the Council of the Royal Agricultural Society passed the following resolution:—"That, in the opinion of the Royal Agricultural Society of England, it is desirable that provision be made in all Universities for the granting of a degree in Science for students of agriculture." The same Society gave evidence before the Royal Commission on the proposed Gresham University for London, and urged that a degree for students in Agriculture should be given by the new University.

Prof. Warington next proceeds to mention what is being at present done in the way of agricultural teaching by British Universities and University Colleges. It appears that the Universities of Edinburgh, Glasgow, Aberdeen, Durham, and Wales, all grant the degree of B.Sc. in Agriculture to students who have successfully passed examinations in agriculture and in the sciences connected therewith. The scheme for agricultural instruction at Cambridge did not succeed in passing the Senate; this University now grants a diploma in Agriculture, the examination for which is open to all-comers. About one half of the University Colleges in England give a complete course of agricultural teaching. Besides these, there are the purely agricultural colleges, to which many additions have recently been made by the County Councils.

The question is then asked, Does this great extension of agricultural teaching in recent years meet all our requirements? The answer is that it does not.

"A real effort is being made to instruct and elevate the farmer and the more intelligent of the labouring class, while the landowner, who finds his education at Oxford or Cambridge, is left without the opportunity of fitting himself for his subsequent duties, and consequently cannot be expected to act the part of a wise leader in the march of improvement which has become so necessary. In the Universities of Oxford and Cambridge there are, I suppose, about 5000 undergraduates, of whom a considerable proportion will in after life have the management of land. A proper provision for the teaching of agriculture in these Universities would, I believe, do far more to improve the condition of agriculture in this country than is effected by all the Government grants distributed by the Board of Agriculture."

Prof. Warington considers, in conclusion, what may be usefully done at Oxford in the direction just indicated. The twelve annual lectures required by statute from the Sibthorpian Professor, unconnected as they are with any examination or degree, are productive of little good. He does not ask that the University should institute a degree in Agriculture, or even that they should at present deal with the subject in any large or comprehensive way. The proposal is that Agricultural Science should be placed among the science subjects, of which two may be selected as part of the final examination for a Pass degree. This plan would merely require the provision of additional lectures, so that agricultural science might be taught throughout the whole academic year. If this modest scheme were adopted the agricultural teaching would become effective, being tested by examination, and leading to that goal of all University men—a degree.

We do not wish to express an opinion on the details of a University scheme; but we heartily wish success to Prof. Warington's proposal. The function of a University is the education of the mind, and the propagation of knowledge; and such an important branch of knowledge as agricultural science should certainly find a place in our schemes of University education.

DR. KOCH'S REPORTS ON RINDERPEST.

THREE reports have now been published by Dr. Koch on Rinderpest. The Cape of Good Hope *Agricultural Journal* for January 14, reprints the first two, whilst the third has appeared in the weekly edition of the *Cape Times* of February 16. The first is dated December 9, four days after Dr. Koch arrived at Kimberley, and the second and third, January 3 and 31 respectively. All hail from Kimberley, which city Dr. Koch has made his headquarters for the present. The scientific experiment station, which has been arranged and fitted up for him, is situated about two miles out. Dr. Edington's research station is at Taungs, where it is stated that the inhabitants have lost as many as 20,000 head of cattle from the pest. It will be remembered that Dr. Edington has discovered and cultivated certain micro-organisms which he believes to be the virus of cattle plague, and Dr. Koch is carrying out some experiments with cultures, placed at his disposal by Dr. Edington, to ascertain what, if any, part is played by them in the disease. Elaborate precautions have had to be taken at the Victorian Compound, Dr. Koch's station, to avoid accidental infection of the animals under observation, which would entirely vitiate the inquiry. Dr. Koch provided himself with blood and other materials obtained from plague-stricken animals, and with these he has already carried out a large number of inoculation experiments. In the first instance an efficient method had to be discovered of infecting animals artificially with the disease, for the methods hitherto employed were not attended with the desired success. Koch, instead of using the secretions of infected animals, has employed hypodermic injections of blood taken from rinderpest victims, and this method has proved extremely successful. All efforts so far to find, whether by cultivation, or microscopical examination, a specific micro-organism in the blood have proved fruitless; neither has any specific microbe been discovered among those abundantly present in the mucus from the nose, the secretions, and other mucous membranes. Dr. Koch has no intention of abandoning the search, but at present his efforts are concentrated upon finding a process which may attenuate the virus of rinderpest, so as to transform it into an antidote. The first steps in this direction were made by inoculating animals, such as sheep and goats, less susceptible to the disease than other cattle, with rinderpest blood. The symptoms, consequent upon these inoculations, resembled those of a mitigated attack of rinderpest; the blood of these animals inoculated into other sheep and goats also induced symptoms of mild rinderpest, and the hope was raised that after these inoculations had been continued through further generations, the blood of these animals might induce a modified attack of the disease in cattle. This hope proved, however, illusory, for cattle succumbed rapidly to rinderpest after such inoculations. Dr. Koch has also been endeavouring to produce an attenuated virus by chemical and physical means. Rinderpest blood mixed with glycerine appears to suffer some abatement of its virulence, whilst even better results followed the addition of phenol to the virus. Cows inoculated with rinderpest blood and phenol did not contract the disease; moreover, when subsequently inoculated with virulent blood, they remained healthy. These experiments are being continued. A most noteworthy experiment was, however, the dessication of rinderpest blood at a temperature of 31° C. during a period of four days. A head of cattle inoculated with this blood dissolved in water remained perfectly healthy. Unfortunately, however, although the inoculation produced no effect upon the animal, it also afforded it no protection from subsequent infection with fresh rinderpest blood. Of all the animals which have been infected with rinderpest blood at the experimental station, only four have recovered, and Dr. Koch has used them for ascertaining whether the blood of immune animals, for they did not contract the disease when inoculated, possesses any protective power. The results were encouraging, for this blood certainly did exert a distinct immunising action; but it remains to be seen

how long this immunity lasts in animals thus vaccinated against rinderpest. It has been ascertained that neither birds, such as fowls, doves, pigeons, guinea-fowls, and cranes are susceptible to the pest. An eagle and a secretary-bird were fed for weeks on intestines taken from rinderpest animals, but absolutely no ill-effect followed. Dogs and donkeys are also immune, as are likewise mice, guinea-pigs, and rabbits; to pigs only, so far, does it appear possible to transmit the infection. In conclusion, Dr. Koch's investigations with Dr. Edington's plague microbe have proved that the latter is not the cause of rinderpest.

NOCTURNAL AND DIURNAL CHANGES IN THE COLOURS OF CERTAIN FISHES AND OF THE SQUID (LOLIGO), WITH NOTES ON THEIR SLEEPING HABITS.[1]

WHILE investigating the nocturnal habits and colours of some of our native marine fishes, in 1885 to 1887, at Wood's Holl, Mass., in the laboratory of the U.S. Fish Commission, of which I had charge at that time, I made the unexpected discovery that a number of species had the peculiar habit of assuming, while sleeping, a style of colouration quite unlike that seen in the daytime. Numerous other duties prevented me from making as many observations of this kind as I wished, at that time, nor have I since had opportunities to continue them. Therefore I have decided to publish these incomplete observations, with the hope of inducing other naturalists to continue such studies in some of the various zoological stations that are now established.

Most of my observations were made late at night, between midnight and 2 o'clock a.m., when everybody else had retired. The gas jets near the aquaria were turned down so low as to give barely light enough to distinguish the forms and colours of the fishes. Under these conditions, by using great care not to cause any jar of the floor, nor sudden movements of any kind, I succeeded in observing many species asleep. Most fishes sleep very lightly, and are aroused by almost imperceptible vibrations of the air or water. Some of these fishes took unexpected attitudes while asleep.

In many cases the change of colour from that seen while awake, or in the daytime, consisted in a simple increase in the depth or intensity of the colours, the pattern of colours remaining the same. This was the case with several species of flounders. Those that are spotted or mottled with dark pigment showed their markings much more strongly, or in greater contrast with the ground-colour, than by day. Several species of minnows (*Fundulus*), which are marked either with longitudinal or transverse dark bands, have these markings more decidedly black and better defined than by day. The same is true of the king-fish (*Menticirrus nebulosus*), in which there are obliquely transverse dark stripes that come out more strongly at night than by day.

The black sea-bass (*Serranus furvus*) and the sea-robins (*Prionotus palmipes* and *P. evolans*) presented the same phenomena. Several species of trout (*Salvelinus fontinalis*, &c.) were observed to become much darker at night than in the daytime, but I was not sure that any of those observed were asleep at the time.

It is well known that trout, flounders, and some other fishes are able to change their colours, even in the daytime, according to the colour of their surroundings. Therefore a darkening of the colours at night is to be expected, even if not asleep. But in all the cases mentioned above the nocturnal change of colour is of a protective character.

Other fishes, however, show much more remarkable changes. Among these the scup or porgy (*Stenotomus chrysops*) is one of the best examples. This fish, when active in the daytime, usually has a bright silvery colour with iridescent tints. But at night, when asleep, it has a dull bronzy ground-colour, and the body is crossed by about six transverse black bands. When one of these fishes, with this colouration, was awakened by suddenly turning up the gas, it immediately assumed the bright silvery colours belonging to its daytime dress. This experiment was repeated many times, on different individuals, with the same result. As this fish naturally rests among eel-grass and sea-weeds, the protective character of its nocturnal colours is obvious.

A common file-fish (*Monacanthus*, sp.) was observed that presents a very decided change in colour pattern. This species, in the daytime, is mottled with brown and dark olive-green, and the fins and tail are a little darker than the body, but when asleep, at night, its body becomes pallid grey or nearly white, while the fins and tail become decidedly black. These colours are decidedly protective at night, or in a feeble light, among rocks and weeds, where it lives. This and other species of file-fishes, when sleeping, would usually rest on the bottom with the back leaning against the glass of the aquarium, or against a stone at a considerable angle.

The common tautog or black fish (*Tautoga onitis*) has the curious habit of resting upon one side, half-buried among gravel, or partly under stones, and is often curved in strange positions. It is easy to imagine that the flounders originated from some symmetrical ancestral form that acquired, like the tautog, the habit of resting upon one side, at first only when sleeping, but afterwards continually, owing to the greater protection that this habit and its imitative colouration afforded. The one-sided colouration and the changes in the position of the eyes, &c., would gradually follow in accordance with well-known laws of evolution.

The common squid (*Loligo Pealei*) was observed sleeping on several occasions. At such times it rests in an inclined position, on the tip of its tail and on the basal parts of the arms, which are bunched together and extended forward, so that the head and anterior part of the body are raised from the bottom, so as to give room for breathing. The siphon tube is then turned to one side. Under these circumstances the colour is darker and the spots more distinct than when it is active, owing to the expansion of the brown and purple chromatophores.

A. E. VERRILL.

[1] Abstract of a paper read before the American Morphological Society, December 30, 1896. These observations were also communicated to the Connecticut Academy of Sciences, in 1888, but were not published. (Reprinted from the *American Journal of Science* for February.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Junior Scientific Club met on Wednesday, March 3, Mr. A. W. Brown (Ch. Ch.), President, in the chair. Prof. Ray Lankester exhibited and described a specimen of Cladoselache and a cast of a restoration of the skull of Thylacoleo. Both specimens have recently been added to the museum. Dr. J. S. Haldane read a paper on "The Causes of Absorption of Oxygen by the Lungs," which was followed by a lengthy and animated discussion.

CAMBRIDGE.—Dr. S. H. Vines, F.R.S., has been appointed by the Council of the Senate a Governor of the Oxford High School for boys.

The valuable collection of Pyrenean and Alpine plants, numbering about 4000, made by the late Mr. Charles Packe, of Christ Church, Oxford, has been presented by his widow to the University Herbarium.

MR. WILLIAM LAMPSON, who died recently at Le Roy, near Rochester, in the State of New York, left the bulk of his estate, valued at about one million dollars, to Yale University, from which he graduated in 1862.

THE Norwegian Parliament has unanimously decided to appoint Dr. Nansen to a Chair of Zoology in the University of Christiania. It is understood that the duties of the Chair will not interfere with any further explorations of the Arctic or Antarctic regions which Dr. Nansen may be disposed to undertake.

To city and county authorities seeking a means of commemorating the sixtieth year of the Queen's reign, we commend the example of the Royal Reception Committee at Sheffield. This Committee was entrusted with the duty of preparing for the Queen's visit to that city on May 21, and at the same time of arranging a suitable mode of commemorating the Diamond Jubilee, and they have decided that the endowment of the Sheffield University College is the best object. For this end the sum of 30,000*l.* is still required, and the Committee have resolved to invite subscriptions through the Mayor, the Duke of Norfolk.

THE Technical Education Board of the London County Council invite applications for a scholarship in sanitary science of the value of £150 a year, tenable in the pathological laboratory of Claybury Asylum. Candidates must be ordinarily resident within the administrative county of London. In making the selection, preference will be given to a candidate who is a qualified and registered practitioner, and has completed his academic course. The scholar must make such arrangements as to residence as will enable him to devote his whole time to the study of the working and effects of preventable, social and industrial causes of insanity.

DR. M. W. NENCKI, director of the chemical department of the Institute for Experimental Medicine, has, states the *British Medical Journal*, recently celebrated the twenty-fifth anniversary of his appointment as Professor of Pathological Chemistry in the University of St. Petersburg. He was presented by his friends and former pupils with a *Festschrift*, which contains, amongst others, papers by Prof. Thomas Arthus, of Freiburg, and Dr. Kostanecky, of Bern. The Council of the University of Kasan, with which Prof. Nencki was connected at the commencement of his professional career, has elected him honorary member, a distinction which is considered a very high compliment in Russia.

THE following are among recent announcements:—Dr. Pompecki to be curator of the State palæontological collection at Munich; Dr. Noll to be professor of botany at Bonn; Prof. E. Wernicke has been invited to the chair of hygiene at Marburg; Dr. Franz Lafar has been invited to the chair of bacteriology and fermentation-physiology in the Technical High School at Vienna; Mr. Charles D. Walcott to be acting assistant secretary in charge of the U.S. National Museum; Mr. Richard Rathbun to be assistant secretary in charge of the office and exchanges of the Smithsonian Institution; Dr. Julius Aparicio to be director of the meteorological and astronomical observatory at San Salvador; Prof. J. Franz to be director of the observatory at Breslau, and professor of astronomy in the University there.

MAY the many instances of large benefactions to research and education in America, recorded by Mr. George Iles in *The Century* for March, act persuasively upon millionaires, and stimulate a desire to emulate the example. Mr. Iles points out that the first large gift for original research in the United States is that of 500,000 dols. received in 1838 as a bequest from James Smithson, an Englishman, who, strange to say, never set his foot in America; in 1891, another Englishman, Thomas Hodgkins, gave the Smithsonian Institution 200,000 dols. more. In bringing the results of research to the service of the public on the lines of an industrial university, the Pratt Institute in Brooklyn is instanced as doing notable work. With its endowment of 3,500,000 dols. it represents a total gift [of about 4,000,000 dols. On a plane of yet higher educational activity stands the Johns Hopkins University in Baltimore, to which Johns Hopkins gave 3,500,000 dols. The University of Chicago, opened but five years ago, has already received about 12,000,000 dols. as gifts, more than half of it being from Mr. John D. Rockefeller. In 1895 Mr. Rockefeller offered this University 2,000,000 dols. in addition to his previous gifts, on condition that an equal sum should be given to it by 1900. His offer has already resulted in a gift of 1,025,000 dols. from Miss Helen Culver. Mr. Ezra Cornell gave 670,000 dols. to the University which bears his name, and the Hon. Henry W. Sage 1,171,000 dols. The cash gifts to the University aggregate 2,738,000 dols. Columbia University, New York, asked for 4,000,000 dols. to erect new buildings when removing to a new site. It received 350,000 dols. from Mr. W. C. Schermerhorn for a natural science building; 1,000,000 dols. from President Seth Low for a library; and 400,000 dols. from members of the Havemeyer family for the erection of a memorial hall. Before the new wants of the university had been declared, its medical departments received 1,970,000 dols. from the Vanderbilt family. Mr. Anthony J. Drexel gave more than 3,000,000 dols. for the foundation of the Drexel College of art, science, and industry; Mr. Marshall Field gave 1,000,000 dols. for the foundation of the Field Columbian Museum; Clark University was established by a gift of 1,500,000 dols. from Mr. Jonas G. Clark; and many other instances of generosity are mentioned by Mr. Iles. It is pointed out, however, that American science still awaits its adequate physical and chemical laboratory for pure research. Judging from the generous spirit shown by past gifts, the waiting time should not be long.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 18.—"On the Significance of Bravais' Formulæ for Regression, &c., in the case of Skew Correlation." By G. Udny Yule. Received December 14, 1896.

If two variables, x and y, be normally correlated, the means of arrays of x's associated with successive types of y's lie on a straight line, called the line of regression. In the general case of skew correlation, this straight line becomes a curve. If, however, a straight line be fitted to the curve by the method of least squares, the equation to this straight line is identical with the equation to the "line of regression" of normal correlation. Hence the formulæ given by Bravais still remain significant whatever the form of the correlation. If the regression of x on y be positive, large values of x correspond, on the whole, to large values of y, and *vice versâ*. The expression for the standard deviation of the array in normal correlation is, in the general case, interpretable as the standard deviation of the whole series of observations from the line of regression.

Similar interpretations hold good for the cases of correlation between three, four, or more variables.

"On the Iron Lines present in the Hottest Stars. Preliminary Note." By J. Norman Lockyer, C.B., F.R.S. Received January 25.

In continuation of investigations communicated to the Royal Society in 1879 (*Roy. Soc. Proc.* 1879, vol. xxx. p. 22), and 1881 (*ibid.*, 1881, vol. xxxii. p. 204), on the effect of high-tension electricity on the line spectra of metals, I have recently used a more powerful current and larger jar surface than that I formerly employed.

The former work consisted in noting (1) the lines brightened in passing a spark in a flame charged with metallic vapours, and (2) the lines brightened on passing from the arc to the spark. It was found, in the case of iron, that two lines in the visible spectrum at 4924·1 and 5018·6, on Rowland's scale, were greatly enhanced in brightness, and were very important in solar phenomena.

The recent work carries these results into the photographic region. The result is interesting and important, since seven additional lines have been found to have their brightness enhanced at the highest temperature. These, as well as the two previously observed, are shown in the following table, which also indicates the behaviour of the lines under different conditions, as observed by Kayser and Runge (K. and R.) and myself (L.) in the arc, and by Thalén (T.) and myself in sparks:—

Lines of Iron which are enhanced in Spark.

Wave-length.	Intensity in flame.	Intensity in arc (K and R). Max.=10.	Length in arc (L). Max.=10.	Intensity in spark (T). Max.=10.	Intensity in hot spark (L). Max.=10.
4233·3	—	1	—	—	4
4508·5	—	1	—	—	4
4515·5	—	1	—	—	4
4520·4	—	1	—	—	2
4522·8	—	1	3	—	4
4549·6	—	4	5	—	6
4584·0	—	2	4	—	7
4924·1	—	1	3	6	6
5018·6	—	4	—	—	6

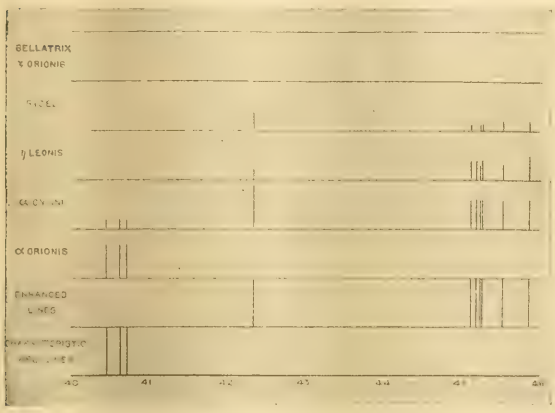
Combining this with former results, we seem justified in concluding that, in a space heated to the temperature of the hottest spark, and shielded from a lower temperature, these lines would constitute the spectrum of iron.

Defining the hottest stars as those in which the ultra-violet spectrum is most extended, it is known that absorption is indicated by few lines only. In these stars iron is practically represented by the enhanced lines alone; those which build up, for the most part, the arc spectrum are almost or entirely absent.

The intensities of the enhanced lines in some of the hottest stars are shown in the appended diagram, and for the sake of comparison, the behaviour of a group of three lines which are among the most marked at lower temperatures, is also indicated. In

addition, the diagram shows the inversion in intensities of the spark and arc lines in the spectrum of a relatively cool star—such as α-Orionis.

The facts illustrated by the diagram indicate that the enhanced lines may be absent from the spectrum of a star, either on account of too low or too high a temperature. In the case of low temperature, however, iron is represented among the lines in the spectrum, but at the highest temperature all visible indications of its presence seem to have vanished.



This result affords a valuable confirmation of my view, that the arc spectrum of the metallic elements is produced by molecules of different complexities, and it also indicates that the temperature of the hottest stars is sufficient to produce simplifications beyond those which have so far been produced in our laboratories.

CAMBRIDGE.

Philosophical Society, February 8.—Mr. F. Darwin, President, in the chair.—On the kathode rays, by Prof. J. J. Thomson. The experiments described in this paper were of two kinds: the first set were on the electric charges carried along the rays, the second on the deflection produced in these rays when they traversed a uniform magnetic field. In the experiments on the electrical effects produced by the rays, the kathode, a plane disc, was placed in a small side tube fused on to a large bulb; between this tube and the bulb there was a thick earth-connected metal disc with a slit in it; a pencil of kathode rays shot through this slit into the bulb. In the bulb on the side opposite to the slit there was an arrangement similar to that used by Perrin in his experiments on the charges carried by the kathode rays; it consisted of two cylinders, one inside the other; the outer cylinder was connected with the earth, and the inner cylinder (which was insulated from the outer) was connected with one pair of quadrants of an electrometer. Slits were cut in the cylinder so that the kathode rays could pass through the slits into the inside of the inner cylinder. The cylinders were placed at a considerable distance from the direct line of the rays, so that unless the rays were deflected by a magnet they did not enter the cylinder. The charge in the cylinder produced by each make and break of the coil was investigated. A slight charge was found to pass into the cylinder even when it was not in the direct line of the rays, due probably to a diffused charge sent out from the tube through the slit into the bulb at each discharge of the coil; this charge was small; it was generally negative, but at high exhaustions was frequently positive. When the rays were deflected by a magnet so as to pass inside the cylinder, the cylinder received a strong negative charge; the charge was large as long as the phosphorescent patch was stopped by the cylinder, small when by the motion of the magnet the patch was removed to one side or another of the cylinder. This experiment seems conclusively to show that there is a flow of negative electricity along the kathode rays. The following experiments show, however, that there must be something besides a stream of negatively electrified particles along the kathode rays. If the coil is kept running the negative charge in the cylinder does not increase indefinitely, it reaches a certain limit and then remains constant, though the kathode rays keep pouring into the cylinder; and further, if the inner cylinder be charged negatively to begin with, then if this charge exceeds a certain amount, though the insulation is perfect when the rays are not playing upon the cylinder, yet as soon as the rays fall upon it some of the *negative* charge escapes. In the experiments on the magnetic deflection of the rays, the rays were produced in a side tube and sent into a large bell jar through a slit in a metallic plate. The bell jar was placed between two coils arranged as in a Helmholtz galvanometer so as to produce a uniform magnetic field. The rays in their course through the bell passed in front of a glass plate ruled into squares. A large number of photographs of the rays were taken in different gases and at various degrees of exhaustion. The following were some of the results obtained. The magnetic deflection of the kathode rays in air, hydrogen, carbonic acid gas and methyl iodide is the same provided the mean potential difference between the kathode and the anode is the same. Coming through the slit there are certain "rays" which are not deflected by a magnet: these have little if any power of producing phosphorescence. The path of the rays for the first part of their course was very approximately circular.—On electricity in gases and the formation of clouds in charged gases, by J. S. Townsend. In the paper on this subject it is shown that the gases, given off when certain chemical actions are going on, have sometimes a very large electrostatic charge. The oxygen and hydrogen given off when a current is sent through a sulphuric acid electrolyte carry with them a positive charge, and when these gases are prepared in a similar manner from a caustic potash cell they carry with them negative electricity. The gases have the property of retaining their electricity in a very striking manner, the fraction of the charge lost when the gas is bubbled through a liquid being very small. When put into vessels and shaken up with sulphuric acid, a large proportion of the electricity still remains in the gas. If a charged gas be left in a flask it loses its charge slowly, for after the space of two hours it is found that $\frac{1}{4}$th of the original charge remains. These gases have the property of condensing a cloud when they get into a moist atmosphere, which can be completely removed by sulphuric acid. The whole process of bubbling through water and forming a cloud and again bubbling through sulphuric acid and removing it can be gone through without losing more than 21 per cent. of the original charge on the gas. The dry gas when it gets into the air of the room will form a perfectly stable cloud in the unsaturated atmosphere. These clouds are very heavy and are easily weighed, and it was found that the weight of the cloud is proportional to the charge; but the proportionality changes with the sign of the charge, the cloud being much heavier in negative oxygen than in positive oxygen, the quantity of electricity being the same in each case.

DUBLIN.

Royal Dublin Society, January 20.—Dr. J. Joly, F.R.S., in the chair.—The Committee, consisting of Prof. W. J. Sollas, F.R.S., Mr. R. Lloyd Praeger, Dr. A. F. Dixon, and Mr. Alfred Delap, appointed by the Royal Dublin Society to investigate the recent bog-flow in Kerry, presented their report, which was communicated by Prof. W. J. Sollas. The report was illustrated by photographs taken on the spot by Dr. A. F. Dixon.—Mr. T. Preston made two communications: (*a*) The parallelogram of forces and the laws of motion; (*b*) Applications of a fundamental method in kinematics and dynamics.—Prof. Hartley, F.R.S., and Mr. Hugh Kamage exhibited specimens of photographs of spectra which illustrate the use of the spectrograph in the minute and accurate analysis of minerals and metallurgical products.

February 17.—Prof. G. F. Fitzgerald, F.R.S., in the chair.—The following paper was read:—On the geology of Slieve

Gallion, in the County of Londonderry, by Prof. Grenville A. J. Cole. The author arrives at the following conclusions: (1) The series of hornblendic and pyroxenic rocks on Slieve Gallion, hitherto described as of metamorphic origin, include a volcanic series of andesite-tuffs and vesicular and compact andesites, together with their deep-seated representatives. The age of this series is "Dalradian," using that term in its widest sense. (2) The granite, also once held to be of metamorphic origin, is an intrusive mass, which has absorbed some of the basic rocks, and has produced quartz-diorites by a process of intermingling. The period of its intrusion was pre-Carboniferous, and probably Middle Devonian, as stated by the officers of the Geological Survey. (3) The basic series west of Cookstown, including the volcanic tuffs of Beaghbeg, is indistinguishable from that of Slieve Gallion, and is almost certainly of the same geological age. The relations of this series to the gneiss that underlies it, have yet to be satisfactorily worked out. The suggestion of Mr. Nolan, that the gneiss became remelted to provide the granite veins above it and the granite mass of Slieve Gallion, deserves the most careful consideration. (4) The occurrence of aplitic granites and eurites on Slieve Gallion, associated with varieties rich in biotite and in hornblende, and the discovery of intrusive veins of pure soda-orthoclase near Oritor, suggest that even the biotite in the granite may have resulted from the absorption of the basic series by a magma that would have otherwise crystallised as an aplite; and, following on this, it is urged that the underlying magmas of the earth's crust may be of far simpler character than has commonly been supposed. Prof. Sollas's investigations at Barnavave, seem to point to the same conclusion. It is then suggested that plutonic rocks, as we ordinarily know them, are phenomena of contact, produced in what are, comparatively speaking, the upper layers of the earth's crust. (5) By a combination of absorption and concomitant or subsequent differentiation, an invading igneous rock may come to occupy the place of a pre-existing rock, and may, in fact, represent it as a pseudomorph, the absorbed matter being drawn off through the molten mass to lower levels.—Dr. F. T. Trouton exhibited photographs taken by Becquerel's new radiation.

PARIS.

Academy of Sciences, March 1.—M. A. Chatin in the chair.—The election of M. Violle, in the Section of Physics, was confirmed by the President of the Republic.—The Perpetual Secretary announced to the Academy the loss it had sustained by the death of M. Weierstrass, Foreign Associate.—Notice on M. Weierstrass, by M. Hermite.—On the residues of some double integrals of rational functions, by M. Émile Picard.—Researches on the uranic rays, by M. Henri Becquerel. Uranium has the property of discharging electrified bodies in air at a distance, the time of discharge being the same for both positive and negative charges. The potential of the charged body was varied between one volt and three thousand volts. For potentials under fifteen volts, the velocity of discharge by the uranium appears to be proportional to the potential, analogous to the law of cooling; but this law is not followed even approximately for very high potentials. Thus, for values between 1500 and 2000 volts, the velocity of discharge is practically constant.—On the histological mechanism of cicatrisation, and on some new fibres, "synaptic fibres," by M. L. Ranvier. The name, "synaptic fibres" is given to fibres special to a cicatrix. These are always firmly attached to the bundles of conjunctive tissue, whatever their origin may have been, have a very variable diameter, and possess the singular property of retraction. Three organic elements appear to be concerned in the formation of synaptic fibres, fibrin, the endothelial cells, and the lymphatic cells. A new theory of cicatrisation is based on these observations.—Remarks by M. Guyon on his work on the therapeutics of urinary diseases.—Observations on the sun, made at the Observatory of Lyons with the Brunner equatorial, during the fourth quarter of 1896, by M. J. Guillaume. The results are summarised in three tables, of which the first two deal with sun-spots, and the other with the distribution of faculæ.—On the theory of surfaces, by M. A. Pellet.—Discharge by the Röntgen rays, by M. Jean Perrin. The effect produced upon a charged conductor by the Röntgen rays is shown to consist of two effects, one depending upon the nature of the gas alone, the other upon the nature of the metal.—Existence of anode rays, analogous to the kathode rays of Lénard and Crookes, by M. P. de Heen.—Photography of the electric radiations of the sun and of its atmosphere, by M. P. de Heen (see p. 447).—Estimation of atmospheric ozone on Mount Blanc, by M. Maurice de Thierry. The air at the summit of Mount Blanc having, on several occasions, showed presence of ozone by qualitative reactions, an attempt was made to estimate the amount quantitatively. The estimation was carried out at Chamonix and at the Grands-Mulets by means of the oxidising action upon an alkaline arsenite in presence of potassium iodide. The amounts found were from two to four times greater than at Montsouris.—Action of dilute nitric acid upon certain metallic nitrates in presence of ether, by M. Tanret.—The commercial transformation of oleic acid into stearolactone and monoxystearic acid, by M. David.—Action of aluminium chloride upon camphoric anhydride, by M. G. Blanc. The acid $C_9H_{14}O_2$, previously described as the result of this reaction, has now been identified with the isolauronolic acid of Kœnigs and Hœrlin, the campholitic acid of Noyes, and the camphothetic acid of Walker.—On a new method of sterilising by heat, under pressure, by M. W. Kühn.—On the larva of *Thrixion Halidayanum*, Rond., of the tribe Tachininæ, parasite of *Leptynia hispanica*, Bol., by M. J. Pautel. The complete life-history of this species has been studied.—Latent and plasmatic life of certain Uredineæ, by M. J. Eriksson. The fungus appears to be derived from certain special corpuscles present in the chlorophyll granules of the host.—Contribution to the physiology of grafting, by MM. Gustave Rivière and G. Bailhache.—On a method of extracting gold from an auriferous mineral, by M. Ém. Serrant.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten*, Part 4, 1896 (physico-mathematical section), contains the following memoirs communicated to the Society.

November 21.—A. Schoenflies: on the representation of "cubes" of various dimensions upon one another. H. Burkhardt: theory of linear groups of point-aggregates on algebraic curves. H. Weber: on a theorem in integral calculus employed in the theory of numbers. E. von Weber: on linear connexes. W. F. Osgood: on non-uniform convergence and the integration of series term by term. W. Voigt: kinetic considerations relating to the theory of evaporation, &c.

December 5.—P. Stäckel: on Goldbach's empirical theorem that every even number may be presented as the sum of two primes.

December 19.—P. Bachmetjew: results of an inquiry on the dependence of electrical earth-currents on the fluctuations in the level of the ground-water in Bulgaria. O. Wallach: researches made in the Göttingen University Chemical Laboratory; (1) on the absorption of violet rays by certain non-saturated ketones; (2) on new compounds of the fenchon-series; (3) on certain condensation-products of cyclic ketones; (4) synthesis of a partially-hydrated methyl-fluorine. A. Hurwitz: on the quaternionic theory of numbers. Vice-Admiral de Jonquières: two errata in vol. ii. of Gauss's Works.

ST. LOUIS.

Academy of Science, January 4.—Dr. Amand Ravold gave a microscopic demonstration of Widal's test for typhoid fever, demonstrating that after the disease has existed for four days or more the blood of typhoid patients, probably because of some contained antitoxine, possesses the power of inhibiting the motion of typhoid bacilli from a pure culture introduced into it within a period of one hour or less, whereas in normal blood similar bacilli retain their power of locomotion for an indefinite length of time. It was stated that typhoid blood possesses this property, even after having been dried for a period of four weeks or more, so that a few drops obtained from a person suspected of having the disease may be sent to suitable places for applying the test, thus rendering comparatively easy the early diagnosis of a disease which in its early stages presents many clinical difficulties.—Prof. F. E. Nipher gave preliminary results of partially completed experiments, made through the courtesy of the Burlington and Illinois Central Railroads, to determine the frictional effect of trains of cars on the air near them. His apparatus consists of a cup collector supported on a bar capable of sliding in guides on a clamp attached to the window-sill of the car. The bar is thrust out to varying distances up to 30 inches. The mouth of the collector is turned in the direction of motion of the train. The pressure due to the motion is conveyed through a rubber tube attached to the rear of the collector, and passing lengthwise through the bar to a water

manometer. The manometer has a tube with a rise of 4 or 5 in 100, and is provided with a pivotal mounting and a level. The pressure near the train is comparatively small, and increases as the collector is thrust further out. It approaches a limit corresponding to the train velocity at the instant. Prof. Nipher finds the relation between the limiting pressure and velocity to agree exactly with the formula

$$P = \frac{\delta v^2}{2},$$

where v is the train velocity in centimetres per second, P is the pressure in dynes to the square centimetre, and δ is the density of air in C.G. units at the temperature and pressure of the observations. He finds the pressure a maximum when the axis of the collector is parallel to the direction of motion with the mouth to the wind. Turning the collector until its axis makes an angle of about 60° with this position, the pressure reduces to zero. At greater angles the pressure becomes less than atmospheric pressure by an amount which reaches a maximum at an angle of 90°, and passes through a minimum at an angle of 180°, when the collector is in a trailing position. The sum of the coefficients for the two positions of maximum compression and minimum exhaust is almost exactly the same as Langley obtained with a pressure board when exposed normally to the wind. The result shows that a large amount of air is dragged along with the train, the motion being communicated to air many feet away. This air is a source of danger to one standing too near the train when at full speed. One is likely to be toppled over, and the blow of the air communicates a motion of rotation which may cause one to roll under the train if the nature of the ground does not prevent such a result. It was remarked, however, that where trains have a right to run at any speed, no prudent person would stand so near to a train as is necessary in order to be in danger from this source.—The following officers were declared elected for the year 1897 :—President: M. L. Gray. First Vice-President: E. A. Engler. Second Vice-President: Charles R. Sanger. Recording Secretary: William Trelease. Corresponding Secretary, E. C. Runge. Treasurer: Enno Sander. Librarian: G. Hambach. Curators: Julius Hurter, J. H. Kinealy, E. Evers. Directors: M. H. Post, Joseph Grindon. (Signed) William Trelease, Recording Secretary.

AMSTERDAM.

Royal Academy of Sciences, January 2.—Prof. Stokvis in the chair.—Mr. Jan de Vries on accelerations of plane motion.—Mr. Jan de Vries read a second paper on geometrical proofs of arithmetical theorems.—On behalf of Mr. Gegenbauer, of Vienna, on the resultant of two consecutive denominators of a certain regular continuous fraction.—Prof. J. A. C. Oudemans made a communication concerning the contents of the fifth section of his report on the triangulation of Java. Of all the sides, both the primary and the secondary ones, it contains the azimuths and the distances. According to the author's calculations, the latter ought to be increased by about two-millionths, to be reduced to mètres des Archives, but by about four-millionth, to reduce them to mètres Internationaux. It is true that the "Comité International," trusting to measurements executed by the "Commission mixte," assumes the above-mentioned standards to be equal in length (though this equality has not been controlled by direct comparison), but the measurements carried out by the Netherlands Committee for the mètre led to the result that the mètre International is shorter than the mètre des Archives by more than 2 μ. At the close of the work the wish is uttered "that the Comité mixte may as yet decide to execute a series of direct comparisons at 0° C. and at high temperatures, between the mètre International and the mètre des Archives.—Prof. Lorentz, on behalf of (*a*) Mr. A. Smits: Measurements with the micromanometer. This instrument, with which differences of pressure as small as 1/4000 mm. of mercury can be observed, consists of a U-shaped tube, the upper parts of whose legs are widened. It contains two fluids, viz. aniline in the lower and narrower part, and upon it, on either side, a quantity of water, whose surface is in the wider part of the tube; the position of the plane separating the two fluids is read with a kathetometer. The object of the research (conducted in the Utrecht Physical Laboratory) was to determine the difference between the vapour pressure at 0° C. of pure water and that of very dilute solutions. For this purpose it was necessary to exhaust the manometer with a mercurial air-pump, some oil being poured on the water on both sides, and to arrange suitable connections either between the two legs or between them and bulbs containing water and a solution. For all these connections mercury joints were employed. Bulbs containing P_2O_5 and H_2SO_4 served for drying, the latter substance at the same time for the absorption of aniline vapour. The measurements were made with solutions of NaCl, KOH, and cane-sugar, the number of gramme molecules in 1000 gr. of water varying in the first case from 1·83 to 0·020, in the second case from 2·64 to 0·013, and in the last case from 1·88 to 0·021. The coefficient i in Van 't Hoff's well-known formula was found to be constant, by 1 for the sugar solutions, but the two other substances yielded values diminishing with decreasing concentration. The extreme numbers were 1·77 and 1·40 for NaCl and 2·17 and 1·5 for KOH. (*b*) Prof. V. A. Julius (Utrecht) on the question: Is the maximum vapour pressure solely a function of temperature? After having discovered the causes of the irregularities presented by the micromanometer in the first stage of Mr. Smit's experiments (a trace of aniline vapour sufficed to prevent the regular condensation of the vapour of water), the author could put to a very severe test the opinion expressed by Wüllner and Grotrian (*Wied. Ann.*, vol. xi. p. 545), according to which a vapour can be compressed above what is commonly called its maximum tension, even though a certain quantity of the liquid be present. Experiments with water and a solution of NaCl at 0° C. did not confirm this view. A space containing a sufficient amount of the liquid and filled for the remainder with saturated vapour, could be diminished by $\frac{1}{2}$ of its original volume. In this way a temporary elevation of pressure was produced, but in a short time the original pressure was re-established by condensation. A change of pressure as small as 1/18000 of its value could have been detected.—Prof. Van der Waals presented for publication in the Academy's *Proceedings:* (1) On behalf of Prof. Kamerlingh Onnes a paper, by Mr. L. H. Siertsema, on an investigation carried out in the Leyden Physical Laboratory, concerning the influence of pressure upon the natural rotation of the plane of polarisation in solutions of cane-sugar. (2) On behalf of Prof. C. A. Lobry de Bruyn and Mr. W. Alberda van Ekenstein, a communication to the effect that the chitosamine from chitin (hitherto wrongly called glucosamine) can be obtained in the free and the crystallised state from the hydrochloric salt and methylalcoholic sodium. It easily changes into another crystalline body, which can be prepared direct from fructose (levulose) and methylalcoholic ammonia. Consequently there is a relation between the last-mentioned sugar and that from which chitosamine is obtained. With silver carbonate HCl chitosamine yields through oxidation a substance, which with phenyl-hydrazine directly gives abundant glucosazon at about 70°, and so it may be glucoson (which is a keton-aldehyde). (3) On behalf of Mr. D. F. Tollenaar, a paper on some experiments with two kathodes, square aluminium plates, the distance of which could be varied. The phosphorescence figures on the wall of the globular screen consisted of a zone of very intense green, bordered on either side by two rings. By changing the intensity of the current towards one of the kathodes, the motion of one of the rings was found to obey the rules of deflexion figures given by Goldstein, but the other ring behaved quite differently. When a triangular or square plate was used, and a metal globe as screen, remarkable shadows were obtained, viz. a triangle and a square respectively, which looked as if turned through angles of 60° and 45° with respect to the kathode (4) On behalf of Mr. S. Krüger, S.J., a paper on the ellipsoidal forms of equilibrium of a revolving homogeneous liquid body. Prof. G. H. Darwin (*Proc.* Roy. Soc., xli.) does not sufficiently account for the method of disregarding errors, which he proposed in the case of very elongate ellipsoids. The kinetic energy of the revolving motion in the case of Jacobi's ellipsoid does not become a maximum "when the length of the ellipsoid is about five times its diameter" (*l.c.*, p. 334), but when the ratio of the longest to the shortest axis is about $9\frac{1}{2}$. When the halves of the axes of Jacobi's ellipsoid are represented by a, b, and c, and this series of forms of equilibrium is continuous, so that $a^2 - b^2/a^2 - c^2$ increases from 0 to 1, then an infinitely great number of bifurcation forms (Poincaré, *Acta mathem.*, vii.) are met with, but *not any one of these figures is found as long as* $a^2 - b^2/a^2 - c^2 \leq \frac{3}{4}$. The limit form of the ellipsoids of revolution is at the same time a bifurcation form, with a series of non-ellipsoidal forms of equilibrium.

DIARY OF SOCIETIES.

NEW WORKS ON BOTANY.

An Introduction to Structural Botany. Part II. *Flowerless Plants.* By D. H. Scott, M.A., F.R.S., &c. Pp. xv + 312. (London: Adam and Charles Black, 1896.)

Physiologische Pflanzenanatomie. Von Dr. G. Haberlandt, Prof. d. Bot. an d. k.k. Universität Graz. Zweite, neubearbeitete u. vermehrte Auflage, mit 235 Abbildungen. Pp. xvi + 550. (Leipzig: Verlag von W. Engelmann, 1896.)

IN these days, when new text-books of various kinds are being poured out more or less indiscriminately from the press, it is a pleasure to be able from time to time to say of some of them that their own intrinsic merits furnish a complete justification for their existence, and we can with confidence make this assertion in respect of the two books which form the subjects of this notice.

Botanists who are engaged in teaching will welcome the appearance of the second volume of Dr. Scott's text-book, for it is just the sort of work to put into the hands of the elementary student. The first volume, we happen to know, has been extremely well received, and this new one, which deals with the flowerless plants, merits an equal measure of success.

The Vascular Cryptogams are illustrated by a selection of well-chosen types, and these are fairly completely described, instead of being treated in that note-book fashion which is only too common in many elementary books. The Liverworts, amongst the Bryophytes, are illustrated by an account of *Pellia*, a type more suitable in every way than is *Marchantia*, which usually does duty in this connection. Indeed, except for the fact that the latter plant happened to have been somewhat carefully studied by Mirbel, and used later by physiologists, it is difficult to understand how it came to be elevated to the position of a Type, which its complex and highly specialised structure render it eminently unfit to occupy.

The Algæ are liberally represented by nine well-selected genera. We could, perhaps, have wished that the term *asexual*, as applied to the ordinary zoospores, might have been replaced by some other word, *e.g. non*-sexual. Students are often misled by the use of the adjective *asexual* into imagining the bodies referred to are all homologous, both mutually, and also with such structures as the spores of vascular cryptogams; whereas in many cases they are more correctly to be compared with the various forms of *vegetative* reproductive bodies occurring in these plants. A transitional form is well exemplified in the gemmæ of *Aneura*. Possibly in instances like that of the four zoospores issuing from the oospore of *Œdogonium*, these cells do really represent the asexual spores of the higher cryptogams.

The book contains far more than a mere description of a number of types; the subject-matter is kept well in hand, and a comparative and synthetic method of treatment runs through it all, thus arousing and sustaining the interest of the reader by enabling him to grasp the proper relationship of one group of facts with the rest. In short the book is deserving of the highest praise, and it will have a useful and, we hope, a successful career before it.

Twelve years have passed away since the first appearance of Prof. Haberlandt's "Physiologische Pflanzenanatomie," which was written as a protest against the one-sided way in which anatomy was commonly studied and taught. Influenced chiefly by the brilliant researches and expositions of Schwendener, his object was to show that the principles laid down by the Berlin professor could be extended and applied to all departments of the minute structure of plants—that there everywhere exists a close connection between the anatomical structure of an organ and the special functions which it may be called upon to discharge. And amongst the varied lines of development into which modern botany has broken out, few have been prosecuted with greater vigour, or explored with such fruitful results, as that one of the "biology" of plants, of which the subject-matter contained in the book before us represents one branch.

The advance here indicated is due, in a great measure, to the happily increasing custom on the part of botanists to travel in countries other than those of Europe. The differences between the vegetation of the temperate and tropical lands strike one at every turn; the strenuous conditions of competition under which the tropical plants coexist appeal at once to the senses, and enable one vividly to realise the delicacy with which each organism must be adjusted to its whole environment. And the same is none the less true when the difficulty of existence is more directly correlated with physical and climatal surroundings than with the aggressive inroads of Esau-like neighbours.

And thus it has been brought about that the study of anatomy, from a physiological or biological point of view, has come to-day to possess an interest and importance far transcending that to which it could lay claim twelve or fifteen years ago.

But just because of the seductive fascination which this aspect of the study exerts on most students of botany, it may not be out of place to emphasise the fact that there is another side to the matter. It is quite possible to attach too much weight to the consideration of the more directly *adaptive* nature of plant structure, while paying too little heed to the fact of the persistence or inheritance, often through a wide range of genera, of *types* of tissue arrangements. For anatomy has a phylogenetic as well as a physiological side, although, save in the broadest features, this is not perhaps so readily discerned in plants as it is in animals. For example, the course of differentiation of the wood in the stems of vascular plants, and the consequent relations of the protoxylem to the later formed woody elements, is astonishingly constant for even large groups of genera or species, and in many cases it affords far surer indications as to natural affinity than most of the external characters by themselves would provide. And yet it would often be difficult to indicate the special advantage which one or other arrangement confers on its possessor; indeed, it is not impossible that it is to this very indifference that its value from a taxonomic point of view is to be attributed.

No doubt, ultimately, the histological no less than the grosser external peculiarities of al plants have been

evolved as the result of the selection of favourable lines of variation; and the constant need of ready adaptation has even resulted in the acquirement of a relatively large "modulus of plasticity" (if the expression may be allowed) in the case of the individual plant, both in respect of its inner and of its outer characters. And it is just this, coupled with the admittedly adaptive nature of the tissues and their elements, which renders it difficult to appeal to the results of anatomical investigations in attempting to solve questions of affinity. But enough has been said to show that anatomical characters have each and all to be judged on their own independent merits; and if proper caution be employed in their discrimination, they are found, after all, to be not different in kind from the characters which are regularly employed by systematists. At the same time, as was said at the outset, it is assuredly the biological, rather than the (perhaps no less important) phylogenetic, aspect of anatomy which most forcibly appeals to the greater number of students, and it is from this point of view that the subject is treated by Prof. Haberlandt.

The new edition is in many respects a great improvement on the old one. It contains 550 pages as against 398, and the number of illustrations has been increased from 140 to 235. As regards the latter, however, it must be confessed that new blocks would have been a very great improvement, the sadly-worn figures in the present edition comparing very unfavourably with those of 1884.

The extension of the book has been chiefly due to the incorporation of new matter; but in several places we note that whole paragraphs have been recast in order to bring their contents into line with the present state of our knowledge. The book as it stands may fairly claim to be up to date, at any rate so far as German literature is concerned. We observe, however, that for the most part reference to work done in this country is conspicuous by its absence, and the name of one of the few English authors who are referred to appears (doubtless by an overlooked printer's error) under a Germanised form. But it would be ungracious to continue to pick holes in a work which in nearly every respect is admirable, alike in its method and its matter, and which will earn for its author the gratitude of all who are seriously interested n botany.

J. B. F.

EXPLORING IN THE NEW ZEALAND ALPS.

Pioneer Work in the Alps of New Zealand: a Record of the First Exploration of the Chief Glaciers and Ranges of the Southern Alps. By Arthur E. Harper, B.A. Pp. xvi + 336. With maps and illustrations. (London: T. Fisher Unwin, 1896.)

TRAVELLING in the Alps of New Zealand is much rougher and more difficult work than in those of Europe. Inns are all but unknown, chalets and club-huts non-existent; guides, even porters, not to be obtained; the weather is more unsettled and stormy. Mr. Harper is evidently the right man for the work. He is strong and enduring, patient and resolute, not daunted by difficulties or dangers. His opportunities for obtaining a knowledge of the Southern Alps of New Zealand have been exceptional, for, after making holiday expeditions in the Tasman district, from 1889 to 1892, he was employed by the Government, in the three following years, to explore the valleys and glaciers of the west coast of the south island. Thus his book differs from that by Mr. FitzGerald, which we lately noticed, in being one of exploration rather than of mountain climbing. On this point, as we can see from the present volume, and from a correspondence in the *Alpine Journal*, some little soreness has been created, particularly in regard to a certain pass lying to the north of Mount Sefton, by which the chain can be crossed without any serious difficulty.

Mr. Harper, in the earlier part of his book, gives an excellent description of the physical geography of the Southern Alps of New Zealand. As a mountain chain they resemble the Pyrenees more closely than the Alps of Europe; they are rather more elevated than the one, but distinctly lower than the other. Mount Cook, the culminating summit (which Mr. Harper tells us ought not to be called Aorangi, for it has no native name), only reaches 12,349 feet above sea level, about the height of the well-known Cima de Jazi in the Zermatt Alps. Yet, though the higher region of the Southern Alps lies between latitudes 43° and 45° S.—say, for instance, between Turin and the north end of Corsica—the snow-line comes down to between 6000 and 6500 feet, and occasionally, under rather exceptional circumstances, it is as low as 5000 feet. The same holds with the ice streams; the Tasman glacier on the eastern side ending at 2354 feet, and the Franz Josef, on the western, at only 692 feet above sea-level. But the mean annual temperature is nearly the same in both regions, so that the difference is mainly due to greater precipitation, which in the higher part of the ranges is probably equivalent to a rainfall of at least 140 inches, for it is 126 inches at Hokitika on the western coast.

Mr. Harper, as he regretfully admits, knows but little geology; still he is a close observer, and has placed on record some interesting facts about the New Zealand glaciers, their rate of motion and distribution. They also, as is well known, once extended far beyond their present limits; the erratics, which they have left in the Westland valleys, are often of enormous size, and the old moraines are on a great scale. One of the Cascade moraines once extended some distance out to sea. The glaciers from the mountains, in Mr. Harper's opinion, formerly debouched from the valleys, and spread out laterally on the lowland, either becoming confluent or, at any rate, covering a very large area; on their retreat they left both districts covered with huge piles of moraine débris, from which the valley terraces were cut by the rivers. The facts mentioned by Mr. Harper make this inference a very probable one. The Cascade moraine, he says, is stratified, and sea-shells are found in some of the layers well inland. A few more particulars about this stratification would have been welcome, especially as to its nature and height above the present sea level. Stratification, no doubt, is sometimes exhibited by the older moraines in the Swiss Alps; but this, so far as we have seen, is always faint. All talus heaps have a slight tendency to assume this structure, owing to a kind of sorting process which goes on among their materials; but the occurrence of marine shells seems to indicate a submergence, during which the ice terminated actually in

the sea; for in this case the most enthusiastic glacialist can hardly summon an ice-sheet from the "vasty deep" to scrape shells from the sea-bottom, and deposit its collections at the foot of the New Zealand Alps.

Mr. Harper had ample opportunities of studying the natural history of the country, and of these he has made good use. The birds, especially the wekas (a kind of rail) and the keas (a mountain parrot), are still very common in some valleys, and are amusing on account of their insatiate curiosity. But from others they have disappeared almost entirely. Man is their destroyer, though not directly; for this has happened in districts which have hardly ever been visited. But the miner often keeps a cat, and, like the Londoner, is apt, when quitting an abode, to leave the animal behind; so it has to feed itself, and becomes a bush-ranger. Weasels also have been introduced into the island; so the birds of New Zealand, especially those which are poor flyers, are having a bad time. The shepherd will view with satisfaction the disappearance of the kea, since it destroys sheep. Mr. Harper explains how the bird has acquired carnivorous habits. The shepherds hang up the skins of sheep to dry, and the kea is an embodiment of inquisitiveness, and tries its beak on everything. If the skin has not been carefully cleaned, it tastes the fat, and "when once a kea tastes fat he is a ruined bird, and would sell his soul—if he had one—to get more." Apparently it is wise enough to know the exact position of the most savoury morsel, for the bird settles on the sheep's back, and bites down to the fat about the kidneys. But if some native birds are disappearing, black swans, an importation from Australia, have become abundant, and the rabbit, in certain districts, is getting to be as great a pest as in Australia. Let well alone, is a maxim often as sound in nature as it is in politics. But we must leave Mr. Harper's very interesting and abundantly illustrated volume. It is a valuable addition to our knowledge of the New Zealand Alps, and a well-told story of difficulties overcome and hardships endured with no little pluck and determination.

T. G. Bonney.

OUR BOOK SHELF.

Lehrbuch der Erdkunde für höhere Schulen. Von Dr. Willi Ule. II. Teil: Für die mittleren und oberen Klassen. Mit 12 farbigen und 79 Schwarzdruck-abbildungen. Pp. viii + 404. (Leipzig: G. Freytag, 1896.)

The author of this excellent little text-book has already made his mark in practical geographical work amongst the younger generation of German geographers. He marshals the facts and enforces the descriptions with a firm grasp of general principles which no mere theorist can attain. But he claims no novelty in method, and states that his book is out and out a child of Alfred Kirchhoff's school.

The perspective in which the world's surface is viewed from the German standpoint of Dr. Ule is somewhat interesting, as the following analysis of the space devoted to the different departments shows:—German Empire, 19 per cent.; Europe outside Germany, 31; Asia, 9; Africa, 7; North America, 3; South America, 3; Australasia and Oceania, 3; physical and general geography, 25 per cent. The small space devoted to North America is remarkable, considering the vast importance of the United States for German trade and as a centre for emigrants.

It would be too much to say that the revival of serious geographical study in this country has largely influenced the form of Dr. Ule's book, but it is a fact that his method of treatment approaches that of the most recent English text-books in several particulars. The illustrations are for the most part old friends, but the sketch maps introduced in the text are original and good.

A Manual of Elementary Seamanship. By D. Wilson-Barker. Pp. xii + 120. (London: Charles Griffin and Co., Ltd., 1896.)

This book will be found most useful and handy to the young sailor; for throughout its pages the subject is treated in a thorough manner.

The author does not limit himself to a description of the more general type, but enters into details respecting most parts of a ship, such as hull, rigging, sails, &c.; and not only are sailing ships dealt with, but steamers are treated in the same manner. Several Parts (ii. to iv.) are devoted to the art of rope splicing, knots, lead, log, rigging, anchors, sail-making, sails, and the handling of boats under sail; these, we may add, are also profusely illustrated, thus enabling the reader to more easily grasp some of the explanations given.

A large figure is also inserted, showing the rigging and sails of a full-rigged ship. Part v., on the rule of the road and signalling, includes two excellent coloured plates of flags, and the semaphore, and Morse alphabets; the last two, we are sorry to say, are as yet seldom used in the mercantile marine, although their importance cannot in any way be overrated. The diagram also contains a scheme by which these can be easily remembered.

A useful glossary of sea terms and phrases is also added.

Researches upon the Antiquity of Man in the Delaware Valley and the Eastern United States. By Henry C. Mercer. Pp. 178. (Publications of the University of Pennsylvania, vol. vi. 1897.)

In this monograph, Mr. Henry C. Mercer, curator of the museum of American and Prehistoric Archæology at the University of Pennsylvania, brings together the results of his investigations of an Indian stone blade quarry in the Delaware Valley, a mortuary deposit of Indian skeletons in Maryland, certain shell heaps on the coast of Maine and at the Durham Cave, and a rock-shelter in the Delaware Valley.

The caves explored failed to give conclusive evidence of pre-Indian or geologically ancient man. It is held that nothing has as yet been found anywhere in the Delaware Valley to corroborate the alleged antiquity of the chipped blades from Trenton. Support is given to Mr. W. H. Holmes' contention that the flint specimens from the Trenton gravel are not true implements, but "wasters" or "rejects" cast away by modern Indians whose village sites occupied the surface above the gravel.

Numerous illustrations of specimens from the caves explored accompany the monograph.

The Universal Electrical Directory (J. A. Berly's). Pp. 1114. (London: Alabaster, Gatehouse, and Co., 1897.)

This well-known Directory contains the names of the members of the electrical and kindred industries throughout the world. It is thus invaluable for finding the addresses of electricians, manufacturers, and dealers. The total number of distinct names in the Directory is 22,658, of which 9933 belong to British individuals and firms. For simplicity and facility of reference the names are divided into four groups—namely: British, Continental,

American and Colonial, which are again sub-divided into alphabetical and classified sections; in the case of the British, a Geographical Section has been added, making in all nine sub-divisions.

Photography as a Hobby. "The Popular Photographic Series." By Matthew Surface. Pp. 60. (London: Percy Lund, Humphries, and Co., Ltd., 1897.)

THIS little book is intended for those who amuse themselves with photography. The author shows how many a pleasant hour may be spent with the camera, and describes rambles he himself has made. These are very well illustrated, and the reader will gather from them that it is not necessary to go very far afield for subjects, as these are always close at hand if one only has the capacity for picking them out. The author describes also how, during unfavourable weather, the "hobby" may be carried on in the house. The book is very neatly got up, and will afford those who indulge in photography as a hobby with a pleasant hour's reading.

First Records of British Flowering Plants. Compiled by William A. Clarke, F.L.S. Pp. 103. (London: West, Newman, and Co., 1897.)

TO satisfy commendable curiosity, it is often required to know who first observed a particular plant, when and where it was first found, and how long it has been known as a British plant. The answers to these questions will be found in Mr. Clarke's handy little volume. The earliest notice of each distinct species of British flowering plants has been found by searching through printed botanical works published in Great Britain, and the extracts thus obtained have been brought together in this work. The list contains altogether 1440 species, the nomenclature of which is based upon the eighth edition of the "London Catalogue." The earliest records referred to are from William Turner's works, ranging from 1538 to 1568.

On Human Nature. By Arthur Schopenhauer. Translated by T. Bailey Saunders, M.A. Pp. 132. (London: Swan Sonnenschein and Co., Ltd., 1897.)

HUMAN nature as understood by that most pessimistic of philosophers, Schopenhauer, is here presented in English dress by Mr. Saunders. The essays which make up the book have been selected and translated from Schopenhauer's *Parerga*. They deal with human nature in various aspects, and their tendency is to make a man suspicious of all people, distrustful of all motives, and doubtful whether civilised life is real or only a big masquerade.

Tabellen für Gasanalysen, gasvolumetrische Analysen, Stickstoffbestimmungen, &c. By Prof. Dr. G. Lunge. (Braunschweig: Friedrich Vieweg und Sohn, 1897.)

THESE tables will be found of service in chemical laboratories in which gas analyses, and volumetric determination of gases, are made. One of the tables is for the reduction of the observed volume of a gas to the temperature of 0°, and the other enables the observed volume to be reduced to a pressure of 760 mm. Together the tables thus furnish the means for reducing volumes of gases to standard temperature and pressure.

The Larvæ of the British Butterflies and Moths. By the late William Buckler. Vol. vii. Edited by Geo. T. Porritt, F.L.S. Pp. 176. 22 plates. (London: Ray Society, 1897.)

THE first volume on the larvæ of the British butterflies and moths appeared in 1885; the present volume contains the first portion of the Geometræ, and this group will be completed in vol. viii. The twenty plates illustrating the larvæ described are extremely fine, and the whole volume is a worthy addition to an invaluable series.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Measurement of Pressures in the Bore of Guns.

IT has been stated that many gunpowders which have given fairly satisfactory results in a small bore, have developed dangerous pressure when tried in cannon; and also that similar experiments with cordite showed no signs of any approach to such a "critical point." Further, cordite is said to burn quietly when thrown in boxes of 100 lbs. upon a bonfire, and yet to be as suitable for ordnance as for small arms. But cordite did not prove so tractable on its late trial in Plumstead Marshes. It is plain, therefore, that explosive forces of all powders depend very much upon the conditions under which they are ignited.

Hence arises a pressing necessity for some satisfactory method of determining the maximum explosive force which every adopted powder is capable of exerting when fired in *rifled* guns of small and large calibre. The chronoscopic method of solving the problem was brought forward thirty years ago, under the then Ordnance Select Committee, but I have never met with a single example fairly worked out for a *rifled* gun, so as to show precisely what could be found by that method. My difficulty was stated in NATURE (March 14, 1895), but hitherto without result, except that the President of the British Association, in his address at Ipswich (September 1895), stated that—

"In the gun, by means of electrical contacts arranged in the bore, a *time-curve* of the passage of the shot can be determined. From this the mathematician constructs the velocity-curve, and from this, again, the *pressures* producing the velocity are *estimated* (?) and used to check the *same indications* obtained by other means (p. 29)."

Now, beside the "pressures producing the velocity" of the shot in *rifled* guns, there is an additional force arising from friction, &c., which greatly adds to the pressure of the powder gas tending to burst the gun. Hence, if we denote by P this pressure of the powder gas on the base of the shot, and by F the retarding pressure of friction, &c., at the same instant, then the resultant driving pressure acting on the shot will be denoted by (P − F) at that instant. If now the projectile be made to trace an *accurate* time-curve, it will be possible to deduce from this time-curve the value of the driving pressure (P − F) acting on the shot at every point. But the grand object is to find P, the pressure of the powder gas tending to burst the gun, and not (P − F) the pressure driving the shot, which is given by the chronoscope. Therefore the chronoscopic method of experimenting fails to give the whole pressure of the powder gas, which tends to burst the *rifled* gun; and this method gives nothing which can be "used to check the same indications obtained by other means," simply because (P − F) is not given by other means. The chronoscopic method of experimenting fails when any part of the pressure (F) of the powder gas is not instrumental in producing motion. From what has been said, the chronoscopic method must fail, even under the most favourable circumstances, when *rifled* guns are used.

But the *perfect accuracy* in experiment we have assumed cannot be secured practically. The most critical point is at the instant the shot begins to move. But no chronoscope which registers by *points* can make the smallest pretence to give the initial time-curve accurately.

The only way to find the pressure of the powder gas at any point in the bore of a *rifled* gun is to use a modification of Rumford's or Rodman's method, which measures directly the pressure in the bore at any point.

The vast importance of this subject to the nation at this time must be my excuse for troubling you a second time.

Minting Vicarage, March 4. F. BASHFORTH.

A Powerful and Efficient Means of Driving X-Ray Tubes.

DURING the last few months the limitations of the present induction coil, especially as a means of driving X-ray tubes and vacuum tubes in general, have been so clearly brought before us that we have given the subject considerable attention. It is

true that with some of the new forms of circuit breakers and storage batteries, an induction coil can be made to work fairly well during prolonged runs; but storage batteries are troublesome, and a break that will work on voltages ordinarily supplied for lighting is yet to be made.

The following method of driving an induction coil not only does away with its former disadvantages, but gives a much more powerful means of exciting X-ray tubes. A condenser of considerable capacity is first charged by connecting its terminals to the ordinary lighting mains; it is then disconnected, and discharged through the primary of an induction coil. Any good induction coil can be used in this way with a single change, viz. a new primary. The primary should be a few turns of heavy wire on a finely laminated core.

A six-inch Ritchie vertical coil with a new primary winding of about thirty turns of heavy wire (6 B.S. gauge) gives, when a condenser of 27 micro-farads charged at 220 volts is discharged through its primary, a long thin zig-zag spark, resembling that from a static machine with small condensers. If now some form of rotary commutator be used to charge and discharge the condensers, and this be run at sufficient speed, a continuous discharge of sparks will take the place of the single discharge at the secondary terminals.

The commutator used has six segments. If this is run at 2000 revolutions per minute by a small fan motor, there will be 12,000 discharges through the coil per minute, or 200 per second. At this speed there is a continuous discharge of zig-zag sparks a little over six inches long. We have not yet run the commutator above 2000 revolutions, but there is no indication that we are near the limit of speed. Sparking on the commutator is slight, and the power taken from the mains is but a few ampères.

It is necessary to have the primary of the coil well insulated, not only from the secondary, but its own turns must be well insulated from one another and the core. An easy and effectual way in the case of a vertical coil is to place the laminated core in a glass tube, upon this wind the primary, then place the whole in a large heavy tube closed at the bottom, and fill with oil. Without insulation there is a tremendous brush discharge within the primary. Undoubtedly the efficiency of the coil would be considerably increased by using an oil insulated secondary, but it is questionable whether the gain would be enough to off-set the trouble and dirt of oil insulation.

An X-ray tube of the focus type and proper resistance connected to the terminals of the coil lights up brilliantly, and with a spark gap in series, the length of which seems to make very little difference, shows no indication whatever of anything but a unidirectional discharge through the tube.

Fluorescent screens become brilliantly illuminated. In a darkened room all the bones of the hand and forearm can be distinctly seen on a calcium tungstate screen at a distance of eight feet from the tube. The penetration seems to be unusually strong. The whole of the trunk can be examined with the greatest ease with the tube several feet distant. The hand can be distinctly seen through the abdomen, the most opaque part of the body.

Photographically, X-rays obtained in this way are no less powerful. Excellent fully-timed photographs of the hand can be taken in twenty-five seconds with the tube twelve inches from the plate, photographs not merely showing the outline of the bones, but showing the details of the bones, the finger-nails, tendons, &c. Forty-five seconds is an over-exposure. One of the best photographs of a small object—a pocket-book—we have seen, was taken in less than a second.

It seems apparent that we have a simple method for exciting X-ray tubes that is far more powerful and efficient than any that has yet been used. It is a method that ought to be particularly adapted to the needs of the physician, and requires no more skill or knowledge of physics than the ordinary practitioner can supply.

Semi-Permeable Films and Osmotic Pressure.

Lord Kelvin's very interesting problem concerning molecules which differ only in their power of passing a diaphragm (see NATURE for January 21, p. 272), seems only to require for its solution the relation between density and pressure for the fluid at the temperature of the experiment, when this relation for small densities becomes that of an ideal gas; in other cases, a single numerical constant in addition to the relation between density and pressure is sufficient.

This will, perhaps, appear most readily if we imagine each of the vessels A and B connected with a vertical column of the fluid which it contains, these columns extending upwards until the state of an ideal gas is reached. The equilibrium which we suppose to subsist will not be disturbed by communications between the columns at as many levels as we choose, if these communications are always made through the same kind of semi-permeable diaphragm as that which separates the vessels A and B. It will be observed that the difference of level at which any same pressure is found in the two columns is a constant quantity, easily determined in the upper parts (where the fluids are in the ideal gaseous state) as a function of the composition of the fluid in the A-column, and giving at once the height above the vessel A, where in the A-column we find a pressure equal to that in the vessel B.

In fact, we have in either column

$$dp = -g\gamma dz,$$

where the letters denote respectively pressure, force of gravity, density, and vertical elevation. If we set

$$\frac{1}{\gamma} = \mathrm{F}'(p),$$

we have

$$\mathrm{F}'(p)dp = -g dz.$$

Integrating, with a different constant for each column, we get

$$\mathrm{F}(p_{\mathrm{A}}) = -g(z - \mathrm{C}_{\mathrm{A}})$$
$$\mathrm{F}(p_{\mathrm{B}}) = -g(z - \mathrm{C}_{\mathrm{B}})$$
$$\mathrm{F}(p_{\mathrm{A}}) - \mathrm{F}(p_{\mathrm{B}}) = g(\mathrm{C}_{\mathrm{A}} - \mathrm{C}_{\mathrm{B}}).$$

In the upper regions,

$$\mathrm{F}'(p) = \frac{1}{\gamma} = at$$
$$\therefore \quad \mathrm{F}(p) = at \log p,$$

where t denotes temperature, and a the constant of the law of Boyle and Charles. Hence,

$$at \log p_{\mathrm{A}} - at \log p_{\mathrm{B}} = g(\mathrm{C}_{\mathrm{A}} - \mathrm{C}_{\mathrm{B}}).$$

Moreover, if $1 : n$ represents the constant ratio in which the S- and D-molecules are mixed in the A-column, we shall have in the upper regions, where the S-molecules have the same density in the two columns,

$$\gamma_{\mathrm{A}} = (1 + n)\gamma_{\mathrm{B}} \qquad p_{\mathrm{A}} = (1 + n)p_{\mathrm{B}}$$
$$g(\mathrm{C}_{\mathrm{A}} - \mathrm{C}_{\mathrm{B}}) = at \log (1 + n).$$

Therefore, at any height,

$$\mathrm{F}(p_{\mathrm{A}}) - \mathrm{F}(p_{\mathrm{B}}) = at \log (1 + n).$$

This equation gives the required relation between the pressures in A and B and the composition of the fluid in A. It agrees with van 't Hoff's law, for when n is small the equation may be written

$$\mathrm{F}'(p_{\mathrm{A}})(p_{\mathrm{A}} - p_{\mathrm{B}}) = atn$$

or

$$p_{\mathrm{A}} - p_{\mathrm{B}} = atn\gamma_{\mathrm{A}}.$$

But we must not suppose, in any literal sense, that this difference of pressure represents the part of the pressure in A which is exerted by the D-molecules, for that would make the total pressure calculable by the law of Boyle and Charles.

To show that the case is substantially the same, at least for any one temperature, when the fluid is not volatile, we may suppose that we have many kinds of molecules, A, B, C, &c., which are identical in all properties except in regard to passing diaphragms. Let us imagine a row of vertical cylinders or tubes closed at both ends. Let the first contain A-molecules sufficient to give the pressure p' at a certain level. Then let it be connected with the second cylinder through a diaphragm impermeable to B-molecules, freely permeable to all others. Let the second cylinder contain such quantities of A- and B-molecules as to be in equilibrium with the first cylinder, and to have a certain pressure p'' at the level of p' in the first cylinder. At a higher level this second cylinder will have the pressure which we have called p'. There let it be connected with the third cylinder through a diaphragm impermeable to C-molecules, and to them alone. Let this third cylinder contain such quantities of A-, B-, and C-molecules as to be in equilibrium with the

second cylinder, and have the pressure p'' at the diaphragm; and so on, the connections being so made, and the quantities of the several kinds of molecules so regulated, that the pressures at all the diaphragms shall have the same two values.

It is evident that the vertical distance between successive connections must be everywhere the same, say l; also, that at all the diaphragms, on the side of the greater pressure, the proportion of molecules which can and which cannot pass the diaphragm must be the same. Let the ratio be $1 : n$. If we write γ_A, γ_B, &c., for the densities of the several kinds of molecules, and γ for total density, we have for the second cylinder

$$\frac{\gamma' - \gamma_1}{\gamma_1} = n.$$

For the third cylinder we have this equation, and also

$$\frac{\gamma_1 - \gamma_2}{\gamma_2 - \gamma_3} = n$$

which gives

$$\frac{\gamma_A + \gamma_B + \gamma_C}{\gamma_3} = (1 + n)^2.$$

In this way, we have for the rth cylinder

$$\frac{\gamma}{\gamma_3} = (1 + n)^{r-1}.$$

Now the vertical distance between equal pressures in the first and rth cylinders, is

$$(r - 1)l.$$

Now the equilibrium will not be destroyed if we connect all the cylinders with the first through diaphragms impermeable to all except A-molecules. And the last equation shows that as γ/γ_3 increases geometrically, the vertical distance between any pressure in the column when this ratio of densities is found, and the same pressure in the first cylinder increases arithmetically. This distance, therefore, may be represented by $\log(\gamma/\gamma_3)$ multiplied by a constant. This is identical with our result for a volatile liquid, except that for that case we found the value of the constant to be at/g.

The following demonstration of van 't Hoff's law, which is intended to apply to existing substances, requires only that the solutum, *i.e.* dissolved substance, should be capable of the ideal gaseous state, and that its molecules, as they occur in the gas, should not be broken up in the solution, nor united to one another in more complex molecules.

It will be convenient to use certain quantities which may be called the *potentials* of the solvent and of the solutum, the term being thus defined:—In any sensibly homogeneous mass, the *potential* of any independently variable component substance is the differential coefficient of the thermodynamic energy of the mass taken with respect to that component, the entropy and volume of the mass and the quantities of its other components remaining constant. The advantage of using such *potentials* in the theory of semi-permeable diaphragms consists partly in the convenient form of the conditions of equilibrium, the potential for any substance to which a diaphragm is freely permeable having the same value on both sides of the diaphragm, and partly in our ability to express van 't Hoff's law as a relation between the quantities characterising the state of the solution, without reference to any experimental arrangement (see *Transactions of the Connecticut Academy*, vol. iii. pp. 116, 138, 148, 94).

Let there be three reservoirs, R', R'', R''', of which the first contains the solvent alone, maintained in a constant state of temperature and pressure, the second the solution, and the third the solutum alone. Let R' and R'' be connected through a diaphragm freely permeable to the solvent, but impermeable to the solutum, and let R'' and R''' be connected through a diaphragm impermeable to the solvent, but freely permeable to the solutum. We have then, if we write μ_1 and μ_2 for the potentials of the solvent and the solutum, and distinguished by accents, quantities relating to the several reservoirs,

$$\mu_1'' - \mu_1' = \text{const.}, \qquad \mu_2'' = \mu_2'''.$$

Now if the quantity of the solutum in the apparatus be varied, the ratio in which it is divided in equilibrium between the reservoirs R'' and R''' will be constant, so long as its densities in the two reservoirs, γ_2'', γ_2''', are small. For let us suppose that there is only a single molecule of the solutum. It will wander through R'' and R''', and in a time sufficiently long the parts of the time spent respectively in R'' and R''', which for convenience we may suppose of equal volume, will approach a constant ratio, say $1 : B$. Now if we put in the apparatus a considerable number of molecules, they will divide themselves between R' and R'' sensibly in the ratio $1 : B$, so long as they do not sensibly interfere with one another, *i.e.* so long as the number of molecules of the solutum which are within the spheres of action of other molecules of the solutum is a negligible part of the whole, both in R'' and R'''. With this limitation we have, therefore,

$$\gamma_2''' = B\gamma_2''.$$

Now in R''' let the solutum have the properties of an ideal gas, which give for any constant temperature (*ibid.* p. 212)

$$\mu_2''' = a_2 t \log \gamma_2''' + C,$$

where a_2 is the constant of the law of Boyle and Charles, and C another constant. Therefore,

$$\mu_2'' = a_2 t \log (B\gamma_2'') + C.$$

This equation, in which a single constant may evidently take the place of B and C, may be regarded as expressing the property of the solution implied in van t' Hoff's law. For we have the general thermodynamic relation (*ibid.* p. 143)

$$v\,dp = \eta\,dt + m_1 d\mu_1 + m_2 d\mu_2,$$

where v and η denote the volume and entropy of the mass considered, and m_1 and m_2 the quantities of its components. Applied to this case, since t and μ_1 are constant, this becomes

$$dp'' = \gamma_2'' d\mu_2''.$$

Substituting the value of $d\mu_2''$ derived from the last finite equation, we have

$$dp'' = a_2 t d\gamma_2''$$

whence, integrating from $\gamma_2'' = 0$ and $p'' = p'$, we get

$$p'' - p' = a_2 t\gamma_2'',$$

which evidently expresses van 't Hoff's law.

We may extend this proof to cases in which the solutum is not volatile by supposing that we give to its molecules mutually repulsive molecular forces, which, however, are entirely inoperative with respect to any other kind of molecules. In this way we may make the solutum capable of the ideal gaseous state. But the relations pertaining to the contents of R'' will not be affected by these new forces, since we suppose that only a negligible part of the molecules of the solutum are within the range of such forces. Therefore these relations cannot depend on the new forces, and must exist without them.

To give up the condition that the molecules of the solutum shall not be broken up in the solution, nor united to one another in more complex molecules, would involve the consideration of a good many cases, which it would be difficult to unite in a brief demonstration. The result, however, seems to be that the increase of pressure is to be estimated by Avogadro's law from the number of molecules in the solution which contain any part of the solutum, without reference to the quantity in each.

Changes in Faunæ due to Man's Agency.

PROF. HADDON'S interesting article in NATURE of January 28 certainly deserves serious attention. Probably few naturalists realise the rapid changes which are being brought about through the agency of man. The way in which the Coccidæ (scale-insects) are carried from country to country is amazing; and with them go their hymenopterous parasites in many instances. Thus, in 1894, Mr. L. O. Howard described the chalcidid *Homalopoda cristata* from St. Vincent, W.I.; in 1896 I described *Aspidiotus secretus*—a coccid—from Japan. Later, in 1896, Mr. Howard was able to report that Mr. Green had bred his St. Vincent chalcidid from my Japanese coccid—in Ceylon! Mr. Howard, in 1896, described another chalcidid, parasitic on scale-insects, from Ceylon; and the day he received the separate copies of his paper, he received the chalcidid from the Southern U.S. Aurivillius, in 1888, described a remarkable parasite of Coccidæ bred by him in Sweden; already it is known also from two localities in the United States, and from Ceylon. As early as 1863, Prof. A. Costa described from Italy a remarkable genus of Chalcididæ, after taking great pains to learn that it was unknown in Europe; but, as Mr. Howard has lately shown, it had been described (the very same species) in 1859 by Motschulsky from Ceylon, whence it had undoubtedly been

accidentally introduced into Europe. *Diaspis amygdali*, a very destructive coccid, was described by Tryon in 1889 from Australia; already we knew it also from various localities in the Oriental, Palæarctic, Ethiopian, Nearctic and Neotropical regions! Very many other such cases might be cited, showing that there is great need for speedy investigation, before the data regarding the true habitats of these and other organisms become impossible of discovery, owing to the extermination of some species, and the dissemination of others.

Mesilla, New Mexico, U.S.A., February 12.

Formation of Coral Reefs.

I have read with much interest the description in Nature of the attempt of Prof. Sollas to bore through the rim of the Funafuti Atoll.

I should like to know what ground he has for believing that the soundings obtained by the officers of the ship which conveyed him to the island, support Darwin's theory of the formation of coral atolls; for there does not appear to be any new feature in the section printed with his letter. It is similar to many other sections of atolls in the China Sea and elsewhere, which have been published from time to time by the Hydrographic Department.

As this attempt has failed, it might be well to turn attention to a more accessible part of the Western Pacific.

The Fiji islands are a complete museum of corals, and contain reefs of every sort of formation. Many of these appear to support Darwin's theory. The Lau, or eastern group, has been elevated, and contains some ancient coral reefs many hundred feet above the sea. The island of Naiau is 580 feet high, and has a rim summit of coral enclosing a depression which, if my recollection serves me, is about 200 feet below the top. If Darwin's theory is correct, this ancient atoll must have been first formed by subsidence, and subsequently elevated to its present position. Borings would probably reveal the lost peak not far below the floor of the central depression.

The island of Kambara, 470 feet in height, is of similar formation.

A close geological examination of Naiau or Kambara would, in all probability, end the controversy, for the borings into the base of the island, commencing some hundreds of feet above the sea, but below what I suppose to be an ancient atoll, could be easily undertaken, and ought to prove at once the nature of the foundation upon which the reef rests.

With regard to the concluding paragraph of Prof. Sollas' letter, he has apparently overlooked the fact that a live specimen of reef-building coral (Astræa) has been dredged up from a depth of forty-five fathoms *in the lagoon* of the Tizard bank by Dr. Bassett-Smith, of H.M.S. *Rambler*. This specimen is in the Natural History Museum. W. Usborne Moore.

8 Western Parade, Southsea, February 25.

Chinese Yeast.

A friend has sent me a few ounces of what he calls Chinese yeast, a white substance which, so I understand, possesses the power of converting rice grains into a soluble substance, which is then allowed to ferment until it is converted into alcohol. Perhaps some of your readers could refer me to a more detailed account of the properties of this yeast. I shall be pleased to send samples for cultivation to anybody who would care to undertake it. C. E. Stromeyer.

6 Jedburgh Gardens, Glasgow, March 6.

DINOSAURS.[1]

It is only sixty years ago since George Catlin wrote his "North American Indians," and graphically described the vast herds of bison, numbering millions of individuals, travelling for days together across the rolling prairies; yet we have seen these disappear, like the aborigines, and their places usurped by the "cow-boy," and by countless herds of domestic cattle.

[1] "The Dinosaurs of North America." By Othniel Charles Marsh. Extract from the Sixteenth Annual Report of the United States Geological Survey, 1894–95. C. D. Walcott, Director. Imperial 8vo. Pp. 133 + 414. Pl. ii + lxxxv. (Washington, 1896.)

If we could only wind the clock of Time still further backwards, and make him disclose, with moving-photographic-vividness, some of those earlier Mesozoic scenes on the American continent, or even in our own little island, for that matter, we should find, not herds of bison, but far other cattle, though some wore horns, and were big and ugly enough in all conscience; yet they were mostly harmless, and herbivorous in diet, but belonging to patterns now entirely obsolete, like the old "brown-bess" of our grandfathers' days, only more so.

And, doubtless, it is due to the extreme rarity of preservation of old land-surfaces, as compared with the far more numerous and abundant records of marine areas which have come down to us, that renders their discovery of such paramount interest to the biologist and geologist. The vast physical changes also which they indicate are, undoubtedly, owing to the immense and unmeasured periods which have intervened, filled only by the slow-music of the sea.

Thus, after parting company with Eocene Mammals, such as *Tinoceras*, we take a plunge in the sea of time, and come again on shore to find that all but the tiniest of Mammals are absent, and the land is peopled by huge herbivorous and somewhat lesser carnivorous Dinosaurs in their stead.

Although this strange reptilian order was discovered so early in this century, it is only within the last thirty years that, thanks to Prof. Huxley, we have been led to understand them; and not till 1881, had we a correct notion even of the skeleton of our own famous *Iguanodon*, though Mantell had commenced to record the discovery of its bones in Sussex in 1825.

One of the most curious points about these mediæval animals is, that they make their earliest appearance in the Triassic period, and were first known in North America some sixty years ago, not by their bones or teeth, but by their footprints. These tracks, discovered so abundantly on the fine-grained, often fissile, sandstones of the Connecticut valley area, were at first attributed to birds, although any birds earlier than the Tertiary period were then unknown.

Yet the genius of Huxley had demonstrated (in 1868) that in the Dinosauria we are dealing with a group of reptiles which most nearly approached the flightless birds, not merely in the weakness and smallness of their fore-limbs, but in the structure of the pelvis, the ilium prolonged forward in front of the acetabulum as well as behind it, and the long rod-like ischium and pubis being all strongly ornithic characters; the head of the femur being set-on at right angles to the shaft of the bone, so that the axis must have been parallel with the median vertical plane of the body, as in birds. The metatarsals were free as in young birds, not anchylosed together as in adult ones; moreover, in *Iguanodon* and some other forms met with, the number of functional digits was three, as seen in the foot of *Dinornis*, and in the great majority of living birds, and the number of the phalanges agrees with that in the II, III and IV toes of the Emeu and Rhea, or any other typical bird's foot. So that there is good reason to conclude that the Connecticut footprints, instead of being those of birds, were certainly the tracks left behind by the *bird*-like Dinosaurs of that period.

From the great difference in size between the fore and hind limbs, Mantell and Leidy concluded that the *Iguanodon*, and some others of its kind, may have supported themselves for a longer or shorter period upon their hind-legs. This conclusion was further confirmed by the discovery made by Mr. S. H. Beckles, F.R.S., of huge three-toed footprints occurring in pairs upon ripple-marked surfaces of Wealden sandstone near Hastings, of such a size, and at such a distance apart, as to lead to the conclusion that they were undoubtedly made by *Iguanodon*. Mr. Beckles' discovery has since been confirmed by the observations of Louis Dollo upon the

Bernissart *Iguanodon* in the Brussels Museum, a cast of which may now be seen set up in the British Museum of Natural History, Cromwell Road.

A few detached reptilian remains from the Trias of America had been made known by Dr. Leidy and Prof. Hitchcock as early as 1854 and 1856; but in 1884, Prof. O. C. Marsh obtained for the Yale University Museum a large part of a dinosaur about 8 feet in length, and, later on, a smaller but most complete example, named by him

FIG. 1.—Restoration of *Anchisaurus colurus*, Marsh ($\frac{1}{3}$ nat. size). Triassic, Connecticut. The reptile which is believed to have made the bird-like bipedal footprints upon the Connecticut sandstones.

Anchisaurus colurus, of which five individuals were discovered, all being of carnivorous type, and the oldest known of the division Theropoda. Marsh feels confident that these and other (perhaps herbivorous) forms were the makers of the bipedal tracks met with in such numbers in the Trias of America, for of the presence of birds at this period we have no evidence whatever.

Passing from the Triassic sandstones to the Jurassic period, we have in the various deposits from the Lias of

FIG. 2.—Restoration of a carnivorous Dinosaur, *Ceratosaurus nasicornis*, Marsh ($\frac{1}{6}$ nat. size). Jurassic, Colorado.

Charmouth, with its herbivorous dinosaur, *Scelidosaurus Harrisoni*, to the Inferior and Great Oolite, with its *Megalosaurus*, its *Omosaurus* and *Cetiosaurus* in this country, represented by *Atlantosaurus*, *Ceratosaurus*, *Stegosaurus*, *Brontosaurus*, *Camptosaurus*, *Laosaurus*, and many other well-known forms, discovered and described by Marsh, from the Jurassic beds of Colorado and Wyoming Territory, U.S.A.

We have, in fact, in the Jurassic period, entered upon "the age of Dinosaurs"; and if, as seems now to be the general conclusion arrived at concerning the age of our own Wealden formation—by Seward, from an examination of the plants; by A. Smith Woodward, from the mammals and fishes; by Marsh, from the reptiles—this deposit is also of Oolitic age, and thus another old-land-area must be relegated to the Jurassic, rather than to the Cretaceous epoch, and we may look upon *Iguanodon* as an Oolitic type.

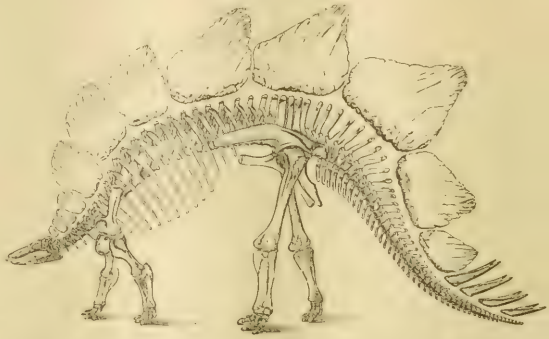

FIG. 3.—Restoration of *Stegosaurus ungulatus*, Marsh ($\frac{1}{30}$ nat. size), a hoofed and armoured herbivorous Dinosaur from the Jurassic of Wyoming. (The size of the brain of *Stegosaurus* was only $\frac{1}{1000}$ that of a young alligator's, if the weight of the entire animal is considered).

Indeed, if the Iguanodon had not been contemporary with the Megalosaur in the Jurassic period, we should have had repeated over again the mournful story of the poor lion, in the Roman amphitheatre, who hadn't any Christian to eat; for the carnivorous Megalosaur of the Oolites would, in that case, have often gone supperless to bed for want of his Iguanodon.

Admitting the strong palæontological evidence which has been brought forward (*Geol. Mag.* 1896, pp. 8 and 69) in favour of the Jurassic age of the Wealden beds; nevertheless the age of Dinosaurs did not terminate until the close of the Cretaceous epoch, for Huxley

FIG. 4.—Restoration of *Brontosaurus excelsus*, Marsh ($\frac{1}{18}$ nat. size, length 60 feet), a huge unarmed herbivorous Dinosaur from the Jurassic of Wyoming. (Estimated when living to have weighed 20 tons? A stupid slow-moving reptile, probably existing upon aquatic or other succulent vegetation.)

described (*Geol. Mag.* 1867, p. 65) a small armed dinosaur (*Acanthopholis horridus*) from the Chalk-marl of Folkestone, and Seeley has determined another (*Orthomerus Dolloi*) from the Maestricht Chalk (*Q.J.G.S.* 1883, p. 248); whilst Marsh has obtained from the Cretaceous beds of the Laramie, in Wyoming, most complete evidence of the entire skeleton of *Claosaurus annectens*, one of a family of herbivorous dinosaurs, in which the cheek-teeth are very numerous and arranged in vertical series, not fewer than 150 being present, whilst the anterior portion of the jaws are narrower and edentulous, but produced in front in a rather wider predentary bone, which was, in

all probability, covered with a horny mandible fitted to meet the strong beak above. Save in the more slender head, and the small and feeble fore-limbs, *Claosaurus* greatly reminds one of *Iguanodon*.

In support of the erect position in which so many of Marsh's animals are represented, it may be well to men-

Fig. 5.—Restoration of *Iguanodon Bernissartensis*, Boul. ($\frac{1}{6}$ nat. size). An herbivorous dinosaur from the Wealden (Upper Jurassic?) Bernissart, Belgium.

tion that *Claosaurus* has "in the median dorsal region, between the ribs and the neural spines, numerous rodlike ossified tendons, which increase in number in the sacral region and along the base of the tail, and then gradually diminish in number and size, ending at about the thirty-fifth caudal. These ossified tendons are well shown in the restoration (Fig. 6), and are of much interest." Similar ossified tendons are seen in *Iguanodon*, and they doubtless served to give attachment to the great dorsal muscles which supported the vertebral column when the animal assumed an upright attitude, or when it used its immense and powerful tail as an oar in swimming across a stream.

Fig. 6.—Restoration of *Claosaurus annectens*, Marsh, an herbivorous Dinosaur ($\frac{1}{9}$ nat. size). Cretaceous, Wyoming.

Another, and possibly the most singular, as well as one of the latest of Prof. Marsh's pets, is the huge *Triceratops prorsus*, one of the quadrupedal dinosaurs, with a skull armed with three horns, two of which were nearly a yard long, and having a bony frill, like an immense Elizabethan ruff, four feet broad, attached to the back of its occiput, the cranium and frill being 6 feet in length from the nose to the hinder border of the bony ruffle.

But skulls of *Triceratops horridus* have been obtained by Marsh, measuring from 7 to 8 feet in length.

Its horns, when found broken off from the skull, were so like the bony horn-cores of some bovine ruminant, as to have been suspected to belong to some very ancient ox; but certainly such three-horned beasts would have been "kittle-cattle" to yoke, or to plough with!

The beak-like edentulous character of the mandibles is very striking, and from the vascular surface of the horn-cores and bony frill, these too, when living, must have been sheathed in a strong horny external covering.

The teeth are very remarkable, having two distinct roots; this is true both of the upper and the lower series. The roots are placed transversely in the jaw, and there is a separate cavity more or less distinct for each of them. They form a single series only in each jaw.

The brain of *Triceratops* appears to have been smaller in proportion to the entire skull than in any known vertebrate.

Although we have nothing in this country which can for a moment compare, in magnitude, with the vast areas in the Western Territories of the United States, often covered to an enormous thickness by great lacustrine deposits of Tertiary, Cretaceous, Jurassic, and Triassic age, full of evidences of old land conditions, yet in our limited island we can show evidence probably of ten successive land-stages from the Wealden to the

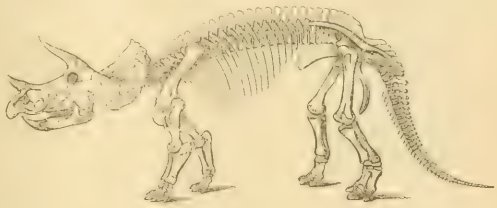

Fig. 7.—Restoration of *Triceratops prorsus*, Marsh ($\frac{1}{30}$ nat. size). Cretaceous, Wyoming. (Length in life about 25 feet, height 10 feet.)

Trias, marked by Mammals or Dinosaurs, by Pterodactyles, and by insects, by plants and carbonaceous shales or coal-seams; so that throughout the lower Secondary series, at least, we can lay down buoys to mark the spots where the old land was situated, though of its actual extent we know but little.

What, we may well ask, were the peculiar conditions of life in the Mesozoic period, which brought about the evolution and continuance through this long æon of such a remarkable land fauna? The associated Jurassic flora may help to solve this query. It consisted largely of Araucarias, *Thujites*, and other Coniferæ, of Cycadeæ, and Palms, of Tree-ferns and many species of Filicinæ, of lesser growth, of giant Equisetums, of liverworts and club-mosses, and some herbaceous and aquatic plants; but, so far as our records tell, no grasses had as yet made their appearance. It is, therefore, certainly reasonable to conclude that most of the herbivorous dinosaurs must have subsisted, almost wholly, by browsing upon the leaves, shoots, and young branches of arboreal vegetation (as did the giant ground-sloths of later Tertiary times in South America), although some may perhaps have fed upon aquatic plants.

This habit doubtless tended to develop their frequent bipedal mode of progression amidst the tall and luxuriant vegetation along the river-banks where they pastured. It also enabled them the better to espy the approach of their enemies, the light-leaping *Hallopus* and *Compso-*

gnathus, and the fierce *Allosaurus* and *Megalosaurus*. These beasts of prey assumed the erect position, not only to observe, but also to rapidly overtake and leap upon their quarry; and it may be, too, that they were able to deceive them by their superficial resemblance to the vegetarians, who were literally taken in by them.

We cannot, in so brief a notice, do justice to the statement that Marsh had discovered an animal with its brain in its tail! "This reminds me"—I was asking the late Captain Speke on his return, in 1864, from Somaliland, what he thought of the Somalis, to which he replied, "They are a splendid race of men, only, unfortunately, their brain is developed at the wrong end of their backbone."

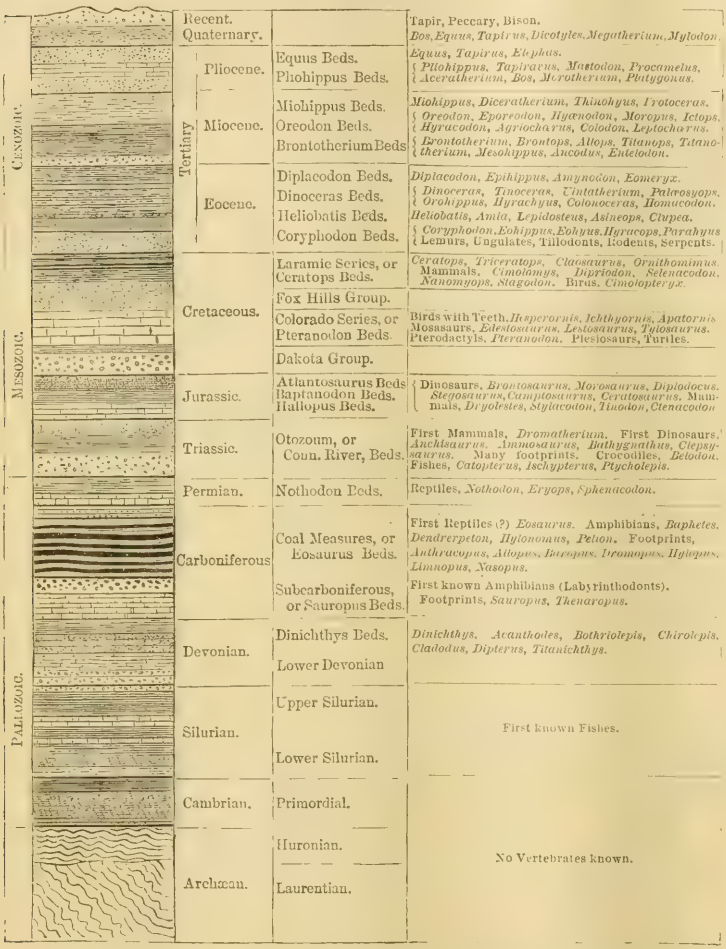

FIG. 8.—Table of British strata, with their North American equivalents, and a list of the vertebrate fossils which are found in them in the United States; drawn up by O. C. Marsh.

labours of Prof. Marsh in this interesting field of inquiry; but those who care to take up this latest volume on Dinosaurs, will find it well repay the perusal. His studies of the brains of these ancient reptiles is alone deserving most careful consideration. The comparison of the brain of *Stegosaurus ungulatus*, with the enormously larger neural cavity in the sacrum, has led to the

The present work by Prof. Marsh is, after all, but a summary of more than fifteen years' labour in the field and in the museum, and may, it is hoped, be followed by even a larger monograph. Nevertheless this volume is a storehouse of facts and figures (there are eighty-four plates!), and will prove of the greatest value to the palæontologist and the biologist.

THE DISCOVERY OF THE LARVA OF THE COMMON EEL.

THE first *Leptocephalus* was discovered in 1763, when a specimen was taken near Holyhead, by Mr. William Morris, and sent to Pennant. Since that time numerous specimens, having similar characters, have been obtained on the shores of Britain, in the Mediterranean, and at the surface of the ocean in various parts of the world. The chief peculiarities of these creatures, which have long been considered much more extraordinary than they really are, are the following. The body is several inches in length, thin and of uniform breadth like a piece of ribbon, very transparent, and unpigmented. The head is small in proportion; there are pectoral fins, but no pelvic, and there is a narrow fin running along the edge of the body, above and below, to the tail. The blood is not red, and there is no air-bladder. Internally the body consists largely of a peculiar gelatinous tissue.

FIG. 1.—*Leptocephalus Morrisii*, the larva of the Conger. (After Couch.)

The suggestion that the *Leptocephali* were the normal larvæ of fishes of the eel family, was first made by the American ichthyologist, Gill, in 1864. In 1886 Yves Delage proved experimentally that *L. Morrisii* changed into a young conger.

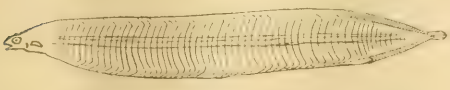

FIG. 2.—*Leptocephalus brevirostris*, the larva of the Eel. (After the original figure in Kaup's Catalogue of Apodal Fish, 1856.)

In 1892 Grassi and Calandruccio published their first paper on these forms, giving a brief and summary account of the results of observations at Catania. They had obtained a large number of living specimens from the harbour of Catania, and had succeeded in keeping them alive for varying periods in aquaria. The specimens belonged to several of the "species" which had previously been distinguished and named, and their metamorphosis into specimens of various species of Murænidæ was traced with complete, or nearly complete, continuity in a number of cases. Thus the complete metamorphosis of *L. Morrisii* into young congers was traced in 150 individuals, larvæ 5 in. long being reduced to congers of only 3 in. *L. diaphanus* became *Conger muræna* (L.), *L. Kölliker*, *Vaxrellii*, *Hæckeli*, and other forms proved to be all stages in the normal development of *Conger muræna mystax*, and *L. Kefersteini* changed into *Ophisurus serpens*.

Leptocephali are most frequently taken in the Straits of Messina, and amongst the forms there obtained is one named *L. brevirostris*, which is remarkable for its small size, and the entire absence of specks of pigment. In 1893 Grassi and Calandruccio announced that they had proved that this particular form was the larva of the common eel. They had not been able to follow the entire metamorphosis in one and the same specimen; but they had verified the most important changes in specimens kept in confinement, and compared all the organs in various stages with those in the perfect form. The greatest length of the larva is 8 cm., or 3¼ in., and the reduction after transformation is never more than 3 cm., so that the smallest elver, or young fully-developed eel, is 2 in. long.

A fuller account of this most interesting investigation was communicated by Prof. Grassi to the Royal Society last year, and is published in the *Proceedings* of December 1896, and also in the *Quarterly Journ. Mic. Sci.* of November 1896. It is well known that in the Straits of Messina strong currents and whirlpools occur. To the existence of these disturbances of the water, the occasional occurrence of various stages in the development of Murænoids in the surface water is to be attributed. As the Leptocephali are captured in company with fish of various species known to belong to the deep-sea fauna, it is inferred that the spawning of the eel and other Muræniдæ, and the development of the eggs and larvæ, take place normally at great depths—at least 500 metres (250 fathoms)—and that the larvæ are carried to the surface with deep-sea fishes by the movements of the water just mentioned. Specimens of *Muræna helena* with ripe eggs, and of adult eels, both male and female, have also been captured under the same circumstances. In these adult eels the generative organs are sometimes more developed than in specimens otherwise obtained, and in some of the males ripe spermatozoa have been observed for the first time. A ripe male conger was described in 1881 by Otto Hermes, and several were kept alive by the present writer in the Plymouth Aquarium, but ripe male eels had never before been obtained.

These mature, or nearly mature, eels are remarkable for the large size of their eyes; and similar specimens, previously obtained from deep water, were described as distinct species by Kaup. The mature male conger is also distinguished by the greater size of its eyes. In the mature eels, also, the skin of the belly is silvery, not yellow, as in river eels.

Raffaele, in his valuable paper on the pelagic eggs and larvæ of fishes in the Gulf of Naples, published in the *Mittheilungen* of the Naples Station in 1888, described five different kinds of pelagic eggs which had certain common characters, and which, in his opinion, possibly belonged to various species of the Muræniдæ. Raffaele described the larva hatched from one of these eggs, and it has the essential characters of a *Leptocephalus*. Grassi considers that one kind of these eggs, which has no oil globules, is that of the common eel. But he believes that the eggs, like the larvæ, are only occasionally brought to the surface, and that they normally remain at great depths.

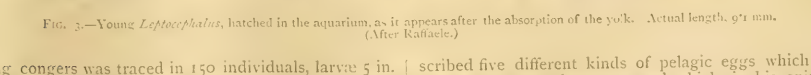

FIG. 3.—Young *Leptocephalus*, hatched in the aquarium, as it appears after the absorption of the yolk. Actual length, 9·1 mm. (After Raffaele.)

It is a curious fact that the larvæ, now identified as those of the eel, are found in greatest abundance in the

stomach of the sun-fish (*Orthagoriscus mola*), which Grassi believes to be a deep-sea species. In the Straits of Messina this fish rarely appears, except in the months from February to September, and the occurrence of *L. brevirostris* is limited to that period. The eggs, which evidently belong to Murænidæ, are found in the sea from August to January; the adult eels in an advanced stage of sexual development have been obtained from November to July; while, lastly, the migration of eels from fresh waters to the sea takes place from October to January. Thus Grassi traces backwards the succession of events in the origin and development of young eels, and reaches the conclusion that the elvers or eel-fare which ascend rivers are already about a year old. The metamorphosis occupies one month. The eels which descend to the sea in winter take some months to ripen their sexual products. The eggs are fertilised in August and following months, and the larvæ are found in the following spring and summer. This agrees with the facts that have been established concerning the conger, the female of which takes about six months to develop her ovaries, and during this period takes no food. The eels which migrate to the sea in autumn have the generative organs in a quite immature condition, and, therefore, could not well be the parents of the elvers, which begin to ascend rivers in the following February. It would appear, however, from Grassi's paper, that he considers the metamorphosis to take place in winter, and that by one year old, he means derived from the larvæ of the previous summer; so that two years would elapse between the descent of the adult eels and the ascent of their progeny.

J. T. CUNNINGHAM.

NOTES

THE death of Prof. J. J. Sylvester, on Monday, deprives mathematical science of a most brilliant mind, and the scientific world in general of one of its foremost workers. The greatness of his genius has long been recognised wherever pure mathematics is studied; for his works command admiration by their originality and breadth of treatment. Eight years ago, Prof. Sylvester was added to the NATURE Series of "Scientific Worthies," and an account was then given of his career and of his more important contributions to mathematical science. We merely call attention to this article now, deferring until our next issue a fuller notice of the life and work of the esteemed investigator just lost to science.

M. G. BONNIER has been elected a member of the Section of Botany of the Paris Academy of Sciences, in succession to the late M. Trécul.

THE library of the late Prof. Kekulé, of Bonn, containing eighteen thousand volumes, mostly on chemistry, has been purchased by the firm of Messrs. Friedrich Bayer and Co., dye manufacturers, Elberfeld.

THE Russian Government has conferred the Order of St. Stanislas upon M. Moureaux, the director of the magnetic work at the Parc St. Maur Observatory. M. Moureaux has also been awarded a gold medal by the Geographical Society at St. Petersburg.

A "DISCUSSION" meeting of the Royal Society will be held on Thursday next, March 25. The subject for discussion is the chemical constitution of the stars, and it will be introduced by Mr. J. Norman Lockyer, C.B., F.R.S., with a communication "On the Chemistry of the Hottest Stars."

THE annual meeting of the Iron and Steel Institute will be held on Tuesday and Wednesday, May 11 and 12. At this meeting the Bessemer gold medal for 1897 will be presented to Sir Frederick A. Abel, Bart., K.C.B., F.R.S. The autumn meeting of the Institute will be held at Cardiff, August 10 to 13.

A REUTER telegram from Christiania states that the Financial Committee of the Norwegian Storthing has unanimously adopted a proposal in favour of granting 4000 kroner to each of Dr. Nansen's twelve companions, and 3000 kroner yearly during a period of five years to Captain Sverdrup, who will be at the head of the next expedition in the *Fram* planned by Dr. Nansen for 1898.

THE Howard Medal of the Royal Statistical Society, together with a cheque for 20*l*., was presented to Dr. James Kerr, at the meeting of the Society on Tuesday, for his essay on "School Hygiene, in its Mental, Moral, and Physical Aspects."

THE Berlin Academy of Sciences offers a prize of 2000 m. for the best treatise on the origin and characters (*Entstehung u. Verhalten*) of the varieties of cereals during the past twenty years. The essays, which may be written in German, French, English, Italian, or Latin, must be sent in by December 31, 1898.

THE American Commission for the selection of a site for a Tropical Botanical Laboratory has now been constituted as follows:—Prof. D. H. Campbell (Leland Stanford University), Prof. J. M. Coulter (University of Chicago), Prof. W. G. Farlow (Harvard University), Prof. D. T. MacDougal (University of Minnesota).

CONSIDERABLE damage to gas and water pipes by electrolysis, due to the escape of the electric current used to propel trolley cars, is noted in Brooklyn. An illustration of the action of electricity was shown in a gas pipe two feet below the rail; the pipe having been found with a gap an inch wide in it, and the edges eaten down to the thickness of a sheet of paper.

PRESIDENT CLEVELAND celebrated the one hundred and sixty-fifth anniversary of the birth of George Washington on Monday, February 22, by setting apart thirteen forest reservations on the recommendation of Secretary Francis and a forestry commission of the National Academy of Sciences appointed by Prof. Wolcott Gibbs, President of the Academy. The reservations have an aggregate area of 21,379,840 acres.

THE Bertillon system of anthropometrical measurements is now applied to criminals in New York City.

THE veteran Italian botanist, Prof. T. Caruel, has retired from the professorship of Botany at the University of Florence.

ON Thursday next, March 25, Prof. W. Boyd Dawkins, F.R.S., will begin a course of three lectures at the Royal Institution on "The Relation of Geology to History." The Friday evening discourse on March 26 will be delivered by Sir William Turner, F.R.S., his subject being "Early Man in Scotland."

WE regret to have to record the death of Prof. Henry Drummond, the author of "Natural Law in the Spiritual World," "The Ascent of Man," and other works aiming at the reconciliation of theological revelation with science and evolution. He travelled in many parts of the world, and his "Tropical Africa" contains a very readable account of his journeys in the interior of that continent. With Sir Archibald Geikie he went on a geological expedition to the Rocky Mountains, and he more recently visited Australia, Java, Japan, and China. He was only forty-six years of age at the time of his death.

THE Report of the Meteorological Council for the year 1895-96 has just been presented to Parliament, and is, as usual,

divided into four sections. (1) Ocean meteorology.—The practice followed by the Office in the collection of information is to supply observers on ships with a complete set of instruments on condition of their return, with a log-book, on the completion of the voyage. The large steamship companies also allow access to their logs, and in some special cases the documents are deposited at the Office. The principal discussions in preparation for publication during the year in question were current charts of the Arctic regions, embracing the area lying north of 60° north latitude, and the meteorology of the South Sea, embracing the area from the Cape of Good Hope to New Zealand. The latter charts, which are the first published for that part of the ocean, will be found very useful by the navigator, especially in connection with the question of the westward homeward route from Australia. Under this head is also included the supply of instruments to distant stations; several sets have been supplied, at the cost of the Foreign Office, for use in Uganda. (2) Weather telegraphy and forecasts.—The work in this branch is constantly increasing from inquiries by the public as to current and past weather, which necessitate a considerable amount of investigation. The number of stations to which storm-warning telegrams are sent has been materially increased during the year by the addition of a number of lighthouses, in accordance with a suggestion made by the Royal Commission on Electrical Communication with Lighthouses. The Council renewed the offer, made in previous years, of sending daily forecasts to agriculturists during hay-making; the results show that the total percentage of useful forecasts amounted to 89 per cent., the same as in the preceding year. (3) Climatology.—This branch includes the discussion and publication of all observations relating to the climate of the British Isles. The publication of the monthly and yearly results for a number of stations for the fifteen years (1876–90) appeared during the year, and forms a valuable contribution to climatological knowledge. (4) Miscellaneous experiments and researches.—The comparison of various forms of anemometers has been made, with the object of determining the factor for converting the records of various instruments to the true velocity of the wind. Experiments have also been made for the measurement of earth temperatures at considerable depths. Rainfall means for a large number of stations are in an advanced state of preparation, and when completed will form a standard of reference in this important subject.

SINCE Jühler and Jörgensen, now nearly two years ago, revived the idea of moulds being the parent of yeast cells, a considerable amount of attention has been directed to the careful reinvestigation of this question. Amongst those who have submitted Jühler and Jörgensen's results to the several tests of experimental inquiry, must be reckoned Messrs. Klöcker and Schiöuning, and in the last number of the *Compte-rendu des travaux du Laboratoire de Carlsberg* these gentlemen publish an extremely interesting memoir entitled "Que savons nous de l'origine des Saccharomyces?" An historical survey of the subject prefaces their own extensive investigations, and we are carried back to the days when Pasteur himself was under the impression that the mould Dematium, so abundantly present on vines, might furnish forth yeast cells, an idea which his later experiments led him, however, to discard. If this Dematium, as Jörgensen claims, is a parent of yeast cells found on grapes, then, provided this mould is present, yeast cells are bound to appear on the surface of the fruit. Klöcker and Schiöuning, following in the earlier footsteps of Chamberland and Pasteur, protected grapes from aërial contamination by enclosing them in glass vessels plugged with cotton wool whilst still attached to the vine. The time selected for their imprisonment was the green stage of the fruit when, whereas Dematium is present in abundance, no yeast cells are to be found. Comparative examinations made later of protected and unprotected grapes respectively, revealed the fact that, whilst the former exhibited plenty of Dematium and not a single yeast cell, the latter, along with the mould, had an abundant crop of yeast cells. The conditions of the two sets of grapes were identical, barring the air being deprived of germs in the one case before reaching the fruit, and not in the other. The experiment was varied in divers interesting ways, but in no single instance was any evidence forthcoming that the yeast cells obtained access to the fruit otherwise than from the surrounding air, the mould Dematium being proved absolutely innocent of any participation in their presence.

MR. P. LEE PHILLIPS speaks truly where he says, in a paper entitled "Virginia Cartography," just issued as No. 1039 of the Smithsonian Miscellaneous Collections, that no records of the past have suffered more from the wear and tear of time than maps. On this account the preparation of a bibliographical description of maps of Virginia—a portion of North America which in early days embraced much of that which is now known as the United States—must have been a very laborious task, and Mr. Lee Phillips is to be congratulated upon having brought his work to a successful conclusion. The maps comprised in his monograph range in date from 1585 to 1893.

WE have on our table several very valuable excerpts from the Report of the U.S. National Museum for 1894, but the limitations of space prevent us from doing more at the present time than call attention to their publication by the Smithsonian Institution. In one of these excerpts Mr. Thomas Wilson describes, and lavishly illustrates, "The Swastika" and its migrations; and makes some observations on the migrations of certain industries in prehistoric times. The Swastika is the earliest known symbol, and consists of a monogrammatic sign of four branches, of which the ends are bent at right-angles, thus . Prof. Max Müller has found evidence for believing that among the Aryan nations the Swastika may have been an old emblem of the sun; but he has also shown that in other parts of the world the same, or a similar emblem, was used to indicate the earth. Mr. Wilson does not attempt to discuss the primitive meaning of the sign, or the place of origin, because they are considered to be lost in antiquity. The principal object of his paper is to present in a compact form all the information obtainable concerning the Swastika, and to trace its possible migrations in prehistoric times. Another of the papers from the U.S. National Museum is on "Primitive Travel and Transportation," by Dr. O. T. Mason. As is the case with all the publications of the Museum, this is illustrated with numerous plates and figures in the text. We must content ourselves now with noting the statement that the mechanical powers, as they are called, seem to have come into vogue in the following order: (1) The weight, for hammers, traps, and pressure; (2) the elastic spring, in bows, traps, machines; (3) inclined and declined plane, in locomotion and transportation; (4) the lever; (5) the wedge, in riving and tightening; (6) the sled, on snow or prepared tracks; (7) the roller, for loads and in machine bearings; (8) the wheel, in travel and carriage; (9) wheel and axle in many forms; (10) pulleys, with or without sheaves; (11) twisting, shrinking, and clamping devices; (12) the screw. The subjects and authors of three other publications just received from the U.S. National Museum are: "A Study of the Primitive Methods of Drilling," by Mr. J. D. McGuire; "Mancala, the National Game of Africa," by Mr. Stewart Culin; and "The Golden Patera of Rennes," by Mr. Thomas Wilson.

THE very important question of the physical and chemical nature of the pigment substances found within the scales of

Lepidoptera, form the subject of a paper, by Mr. A. G. Mayer, in the March number of the *Entomologist*. Experiments have shown that reds, yellows, browns and blacks are always due to pigments. In some cases, greens, blues, violets, purples and whites are also due to pigments, and not, as is usually the case, to structural conditions, such as striæ upon the scales, &c. Concerning the chemical nature of the pigment substances within the scales, little has as yet been made known. The white pigments in the Pieridæ appear to be due to uric acid, and the red and yellow pigments to two closely related derivatives of uric acid. The green pigment found in several species of butterflies and moths has also been shown to consist of a derivative of uric acid. The results of a careful investigation leads Mr. Mayer to believe that the colours of many of the Lepidopteral imagos are derived from the hæmolymph or blood of the chrysalis. It is well known that the most universal colours of the more lowly organised moths are the drab-grey and yellow-drab tints, and these are the colou s which Mr. Mayer found were assumed by the hæmolymph after exposure to the air. The brilliant yellows, reds, &c., are the result of more complex chemical processes; but the colours can be manufactured to some extent by treating the hæmolymph with certain reagents. In connection with the phenomena of pigmentation it is noted that uric acid is never present in the hæmolymph of the imago of Saturnidæ, nor could Mr. Mayer detect it in the drab-coloured pigment of the outer edges of the wings.

ATTENTION may here profitably be directed to a paper which, though at first sight may appear of purely medical interest, has an important bearing upon the results described in the preceding paragraph. We refer to a brochure by Mr. J. Barker Smith, reprinted from the *Medical Press and Circular*, 1896-97 (Baillière, Tindall, and Cox). Mr. Smith's experiments suggest that urates may be excreted by the hair, and that uric acid plays a *rôle* in respiration and in the formation of the red corpuscles from nuclear elements. The discovery of urates in the hair is significant, for it naturally brings into consideration wool, feathers, fur, &c., as to colouration and use, and also adornment and odour with reference to excretion and sex. Should Mr. Smith's results be verified, they indicate that one chemical of necessity determines many common characteristics in a large section of our fauna. Another noteworthy point in the paper is the description of a new and rapid method of estimating urates.

BARON H. EGGERS contributes a paper on the Gulf of Maracaybo to the *Deutsche Geographische Blätter*, referring specially to the asphalt springs of El Menito. The whole region is of great geographical interest, but is little known on account of its extremely unhealthy climate. El Menito itself is a rounded knoll about 1 km. in diameter, and dotted about on its surface is a number of small cones, from which streams a mixture of mud, water and asphalt. The asphalt is in general colder than the surrounding air, and hardens in a few days, usually in a much cleaner and purer condition than the familiar asphalt of Trinidad. The greatest output of asphalt from this region took place in 1885, when it amounted to 161,000 kilogs., but since then the quantity has steadily diminished, chiefly from political causes.

MANY and various are the lakes in the United States, but there is only one which occupies the crater of an extinct volcano; it is the Crater lake of Southern Oregon, lying in the very heart of the Cascade range, and belonging to the great volcanic field of the north-west. A very instructive illustrated account of the features of this lake is contributed to the *National Geographic Magazine* by Mr. J. S. Diller, of the U.S. Geological Survey. The lake contains no fish, but a small crustacean flourishes in its waters, and salamanders occur in abundance locally along the shore. According to observations made by Mr. B. W. Evermann last summer, the temperature of the water decreases from a depth of 555 feet to the bottom (1623 feet). The results suggest that the bottom may still be warm from volcanic heat, but more observations are needed to fully establish such an abnormal condition. Mr. Diller shows that Crater lake not only presents very attractive scenic features, but also affords a most instructive and interesting field for the study of volcanic geology.

MR. SCOURFIELD'S plea for a fresh-water biological station in England is supported by Prof. Dr. Anton Fritsch, who, in a short article in *Natural Science* (March), shows that valuable work is being done on the fauna and flora of fresh water in Bohemia and Germany. Prof. Fritsch hopes that England will soon likewise do her duty to fresh-water biology, by establishing a station where investigations can be carried on. Such an institution would give results of a practical, as well as scientific value. In connection with this subject, and in evidence of the valuable work accomplished at the Biological Station of the University of Illinois, situated at Havana, on the Illinois River attention may be directed to a bulletin just received. By this publication Mr. Richard W. Sharpe makes a noteworthy "Contribution to a Knowledge of the North-American Fresh-water Ostracoda included in the families Cytheridæ and Cyprinidæ."

NO better evidence could be adduced of the valuable services rendered to science by the establishment of a national physical laboratory, than the following list of investigations published within the last few months in *Wiedemann's Annalen*, all emanating from Charlottenburg:—Herr K. Kohle describes Helmholtz's absolute electrodynamometer as constructed during the lifetime of Helmholtz at the Reichsanstalt, and which he has employed to determine the electromotive force of Clark's cell; Herr Willy Wien contributes a mathematical investigation of the formulæ required to determine the constants of the instrument; Herrn W. Jäger and R. Wachsmuth describe a series of experiments on the cadmium cell, including a comparison of its electromotive force with that of Clark's cell, and a determination of the variations of this element with the temperature: Dr. L. Holborn and Herr W. Wien describe some important researches on measurement of low temperatures, including a comparison of the air and hydrogen thermometers; and Herrn M. Thiesen, K. Scheel and H. Diesselhorst give an account of a series of determinations of the coefficient of expansion of water.

As the result of work carried on in the same laboratory, Prof. Friedrich Kohlrausch, of Berlin, contributes to the *Annalen* papers on the following subjects:—On platinum electrodes and determinations of resistance; on the plugs of rheostats; on very rapid fluctuations of terrestrial magnetism; and on a thermometer for low temperatures, and a determination of the coefficient of expansion of petroleum-æther. The latter name is applied to a certain mixture of hydrocarbons whose boiling point is 33°, and specific gravity 0·6515 at 17°. This substance remains fluid down to the temperature of liquid air, when it becomes highly viscous.

IN the *Zeitschrift des Vereines deutscher Ingenieure*, Dr. L. Holborn gives an account of Le Chatelier's thermo-electric element, and shows how it may be applied to the continuous measurement of the temperature of a furnace, thus possessing considerable advantages over the pyrometers in common use. Writing in the *Berliner Sitzungsberichte*, the same physicist describes a number of observations on the coefficient of magnetisation of different kinds of iron and steel, showing that in a feeble field of force the coefficient in question is a linear function of

the temperature. The experiments connected with both of Dr. Holborn's present papers, like those of the two preceding articles, were carried out at Charlottenburg.

THE hostility often shown by farmers to the work of the Technical Instruction Committees of the County Councils may, perhaps, be tempered a little by an examination of a report on manurial trials, conducted by Prof. W. Somerville, during the season 1896, under the auspices of the County Councils of Cumberland, Durham, and Northumberland, and the Durham College of Science. The experimental work furnishes agriculturists in the North of England with very valuable information upon the effect of different manures and mixtures of manures upon crops. It has been proved that though increasing quantities of farmyard, or of artificial, manure will produce increasing yields up to a certain point, the profits per cwt. are greater for a moderate than for a large dressing. The addition of artificial manures to a fair dressing of farmyard manure appears to have exceedingly little, if any, effect upon the crop. This and other results show that there is need for manurial reform in the matter of the combined use of natural and artificial manure. Prof. Somerville has again demonstrated by experiment the extremely infectious character of the "finger and toe" disease; and, as already noted, his experiments with "nitragin" have failed to give positive results; so it is doubted whether the new substance, in its present state, will prove of any service to agriculture.

A QUANTITATIVE study of correlated variation and of the comparative variability of the sexes has been made by C. B. Davenport and C. Bullard, by counting the Müllerian glands in the fore-legs of four thousand swine. The total number of glands on a single leg varies from 0 to 10; and the counting has shown that they are slightly less abundant in the female than in the male. The average numbers of the glands on the right leg and on the left leg, taken without regard to sex, are about equal. As to their variability, it appears that the variants are distributed in accordance with the probability curve, or very nearly so. The degree of variability in the right and left legs is, especially in the case of the male, strikingly similar, being 1·41089 and 1·41083 in the two cases respectively, the difference being within the errors of the method. The males are about 2·5 per cent. more variable than the females. The degree of correlation in the variability of the right and left legs is about ·777. The observations are described in the *Proceedings* of the American Academy of Arts and Sciences (vol. xxxii. No. 4, December 1896).

THE April number of *Science Progress* will contain articles on the "Physiology of Reproduction," by Prof. H. Marshall Ward, F.R.S.; on "Condensation and Critical Phenomena," by Prof. J. P. Kuenen; on "Diseases of the Sugar-cane," by Mr. C. A. Barber, late Superintendent of Agriculture in the Leeward Islands; and on "Coagulation of the Blood," by Dr. Halliburton, F.R.S.

THE volume containing the "Results of Rain, River, and Evaporation Observations made in New South Wales" during 1895, under the direction of Mr. H. C. Russell, C.M.G., F.R.S., has just been published. In addition to the usual statistics, the volume contains Mr. Russell's paper on the "Periodicity of Good and Bad Seasons," already abridged in NATURE (vol. liv. p. 379), and also some instructive diagrams showing the relative values of the rainfall of the Colony for the past six years.

A NEW "Encyclopædic Dictionary of the English and German Languages," edited by Prof. Ed. Muret and Prof. Daniel Sanders, is in course of publication, in parts, by the Langenscheidtsche Verlagsbuchhandlung, Berlin. The work is being issued in two sections—English-German and German-English—and will be completed in about forty-eight parts. The last part of the former section will appear in a few months; the first part of the German-English section has, however, only just been issued. Judging from this part, the Muret-Sanders "Wörterbuch" will, when completed, possess advantages over all existing German dictionaries. The London agents are Messrs. H. Grevel and Co.

MESSRS. WILLIAM WESLEY AND SON have, since 1871, issued a number of excellent catalogues of scientific works, but they have not compiled a better catalogue than the one just published as Nos. 127 and 128 of their "Natural History and Scientific Book Circular." In the ninety-two pages of this list are the titles or more than three thousand works on every subject connected with botanical science, both in its theoretical and applied branches. The works are classified into about fifty groups, and are arranged alphabetically, according to authors, in each group. Great attention appears to have been paid to careful description and correct classification, and we have no doubt that the catalogue will be of real use both to botanists and gardeners.

NEW editions of two standard German scientific works have been received. One is Naumann's "Elemente der Mineralogie" (Leipzig: Wilhelm Engelmann), the thirteenth edition of which has been revised and enlarged by Prof. Dr. Ferdinand Zirkel. Only the first half of this new edition has as yet been published; the second half will appear towards the end of this year.—Kirchhoff's "Vorlesungen über mathematische Physik" (Leipzig: B. G. Teubner) has reached a fourth edition. The first volume, on mechanics, has appeared under the editorship of Prof. Dr. W. Wien. The original work was published twenty years ago, and the two following editions of it—the third in 1883—were seen through the press by the author himself. The present edition of Kirchhoff's "Mechanik" is thus the first which has been issued under the guidance of another.

HERR A. SONNEWALD, veterinary surgeon, contributes a paper of considerable interest to the current issue of *Deutsche Geographische Blätter*, summarising present knowledge of animal epidemics in South Africa, and describing in particular the geographical distribution of the rinderpest. The paper refers specially to the work of Edington and Thompson.

A POINT which strikes one on glancing through the annual report of Mr. Frederick J. V. Skiff, the Director of the Field Columbian Museum, is that a large number of expeditions are sent out by the Museum to collect specimens and make observations. The most important expedition of the year was one which went to Africa, under the direction of Mr. D. G. Elliot, Curator of the Department of Zoology, except ornithology. This party arrived at Aden last September with a splendid collection. Mr. C. F. Millspaugh, Curator of the Department of Botany, began his work last year on the forestry of the Mississippi Valley. The Curator of Geology went on expedition to the Republic of Mexico. He made a complete ascent of Popocatepetl and explored the crater, and ascended Ixtaccihuatl far enough to permit a study of its glacier. A great many mineral specimens and ores were obtained. Mr. G. K. Cherrie, Assistant Curator of Ornithology, spent three months collecting bird skins along the Gulf coast between New Orleans and Corpus Christi, Texas. Nearly one thousand skins were thus added to the North American division of this department. Mr. Miner W. Bruce arrived from Alaska after nearly two years absence, with a collection of 1200 or more specimens illustrating the arts and industries of the Eskimo of Alaska. He has returned again to the North with a commission to add further material, and to extend his work into Siberia. Mr. E. H. Thompson made a report on the recently examined ruins of Xkichmook, accompanied by specimens

and photographs. Vice-President Ryerson and Mr. C. L. Hutchinson, on their trip around the world, procured and presented to the Museum a large and unique amount of material, including Etruscan and Stone Age remains from Italy, Roman terra-cottas, metal and stone work from the Indies, and butterflies from the Himalayas. Mr. Owen F. Aldis invited Mr. O. P. Hay, Assistant Curator of Ichthyology, to accompany him on an excursion to the waters of Southern Florida. Nearly one hundred fine specimens were thus obtained. By sending collectors to all parts of the world in this way, the Field Columbian Museum gives evidence of very great activity. The specimens obtained by its officers will not only serve to enrich the Museum directly, but a large number of them can do so indirectly by exchange.

THE additions to the Zoological Society's Gardens during the past week include two Secretary Vultures (*Serpentarius reptivorus*) from South Africa, presented by Mr. P. Myburgh; two Sacred Ibises (*Ibis æthiopicus*) from South Africa, presented by Mr. Almeda; a Herring Gull (*Larus argentatus*), a Lesser Black-backed Gull (*Larus fuscus*) from Nova Zemlya, presented by Mr. C. L. Rothera; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, presented by Mrs. Anderson; two Crested Porcupines (*Hystorix cristata*), a Griffon Vulture (*Gyps fulvus*) from North Africa, presented by Mr. R. S. Hunter; four Common Rat-Kangaroos (*Potorous tridactylus*, 2 ♂, 2 ♀), seventeen Lesueur's Water Lizards (*Physignathus lesueuri*) from Australia, deposited; two —— Parrakeets (*Psephotus chrysopterygius*) from Australia, four Brent Geese (*Bernicla brenta*, 2 ♂, 2 ♀), European; a Bengalese Cat (*Felis bengalensis*) from the East Indies; four Red-crested Pochards (*Fuligula rufina*, 2 ♂, 2 ♀) from India, three Mandarin Ducks (*Æx galericulata*, ♀) from China; three Summer Ducks (*Æx sponsas*, ♀) from North America; two Rosy-billed Ducks (*Metopiana peposaca*, ♂) from South America; a Japanese Teal (*Querquedula formosa*, ♀) from North-east Asia; five Chiloe Widgeon (*Mareca sibilatrix*, 3 ♂, 2 ♀) from Chili, a Spur-winged Goose (*Plectropterus gambensis*, ♂) from West Africa, purchased.

OUR ASTRONOMICAL COLUMN.

COUDÉ MOUNTINGS FOR REFLECTING TELESCOPES.—For spectroscopic work the reflector is, without doubt, the most ideal form of telescope. Not only does the visual light-grasping power increase very rapidly the larger the aperture, but for the purposes of photography the same is also true. The refractor has, however, as yet the most convenient and comfortable arrangement for observation from the observer's point of view, while with the reflector the observer is not so conveniently situated. That some kind of coudé arrangement can be adopted is, therefore, an important step in bringing these instruments more into use; for not only are reflectors cheap when compared with objectives, but their mountings and the accompanying housing are much less expensive. Prof. Wadsworth, in the February number of the *Astrophysical Journal* (vol. v. No. 2), describes several ways in which the reflector may be coudé mounted, one of which was suggested by the late Mr. Cowper Ranyard, but was not completely worked out owing to his sudden death. Perhaps the two most promising arrangements are (1) when the reflector is of the Newtonian type, and the primary flat is placed at right angles to the axis of the tube reflecting the cone of rays back again on to two small mirrors, one placed just in front of the mirror, and the other in the polar axis; and (2) when the reflector is of the Cassegrain type, and a single small additional mirror is necessary to reflect the rays directly down the polar axis. The latter appears, however, the more simple of the two, but the method of mounting seems somewhat too weak for mirrors of large size. Prof. Hale, in the same number of that journal, discusses the comparative value of refracting and reflecting telescopes for astrophysical investigations, pointing out the superiority of the latter from many points of view, while Mr. Ritchey describes a new method of a support system for large specula.

ON APPARENT AND REAL DISELECTRIFICATION OF SOLID DIELECTRICS PRODUCED BY RÖNTGEN RAYS AND BY FLAME.[1]

THE fact that air is made conductive by flame, by ultra-violet light, by Röntgen rays, and by the presence of bodies at a white heat has been shown experimentally by many experiments. We propose in this communication to give some results bearing on this conductivity of air, based chiefly on experiments of our own.

We have examined more particularly the behaviour of paraffin and of glass.

In our first experiments with paraffin we used a brass ball of about an inch diameter, connected to the insulated terminal of an electrometer by a thin copper wire soldered to the ball. The ball and the wire were both coated to the depth of about one-eighth of an inch with paraffin. The ball was then laid on a block of paraffin in a lead box with an aluminium window, both of which were in metallic connection with the case of the electrometer. By this means we avoided all inductive effects.

The electrometer was so arranged as to read 140 scale divisions per volt.

After testing the insulation the paraffined ball was charged positively and the rays played on it. After two minutes the electrometer reading was steady at 0·5 of the initial reading. The electrometer was then discharged by metallic connection, and again charged positively. Its reading remained steady after three minntes at 0·63 of the initial charge. In the third and fourth experiments the readings after three minutes were ·81 and ·90 of the initial charges respectively.

The ball was next charged negatively. When the rays were played on it a steady reading was obtained after four minutes at ·18 of the initial charge. In the second, third, and fourth experiments the steady readings after four minutes were ·45, ·70, and ·78 of the initial charges respectively.

The paraffin was then removed and the brass ball polished with emery paper; whether the charge was positive or negative, it fell in about five seconds to one definite position, 50 scale divisions on the positive side of the metallic zero, when the Röntgen rays were played on the charged ball.

These experimental results demonstrate that the Röntgen rays *did not produce sensible conductance* between the brass ball, when it was coated with paraffin, and the surrounding metal sheath: and that *they did produce it* when there was only air and no paraffin between them. From experiments by J. J. Thomson, Righi, Minchin, Benoist and Hurmuzescu, Borgmann and Gerchun, and Röntgen,[2] we know that air is rendered temporarily conductive by Röntgen rays, and Röntgen's comparison of the effect of the rays with that of a flame shows that our experimental results are explained by the augmentation of the electrostatic capacity (quasi-condenser) of the brass ball by the outside surface of its coat of paraffin being put into conductive communication with the surrounding lead sheath and the connected metals.

In our second experiments we have endeavoured to eliminate the influence of the varying capacity of this quasi-condenser. For this purpose, we placed a strip of metal connected to the insulated terminal of the electrometer inside an aluminium cylinder; the space between the metal and the cylinder was first filled with air, afterwards with paraffin. The aluminium was connected to the case of the electrometer, and inductive disturbances were avoided by surrounding the copper wire connecting the metal to the isulated terminal with a lead sheath in metallic connection with the electrometer sheath (see diagram).

In our first experiments with this apparatus we had air, instead of the main mass of paraffin, separating the insulated metal from the surrounding aluminium tube, as shown in the diagram, and we had only small discs of paraffin serving as insulating supports for the ends of the metal, and not played on by the Röntgen rays. When the metal thus supported was charged, whether positively or negatively, the Röntgen rays

[1] By Lord Kelvin, Dr. M. Smoluchowski de Smolan, and Dr. J. Carruthers Beattie. Read before the Royal Society of Edinburgh, February 15, 1897.

[2] J. J. Thomson, *Proceedings* R.S.L., February 13, 1896; Righi, *Comptes Rendus*, February 17, 1896; Benoist and Hurmuzescu, *Comptes Rendus*, February 3, March 17, April 27, 1896; Borgmann and Gerchun, *Electrician*, February 14, 1896; Röntgen, Würzburger, Phys. Med. Gesellschaft, March 9, 1896; Minchin, *The Electrician*, March 27, 1896.

diselectrified it in about five seconds; not, however, to the metallic zero of the electrometer, but to a "rays-zero" depending on the nature of the insulated metal and of the metal surrounding it.

With paraffin between the aluminium cylinder and the insulated metal within, as shown in the diagram, the following results were obtained:—

December 30, 1896. 5.30 p.m.—Interior metal charged negatively. Total charge 356.

Röntgen lamp in action and no screen	39	scale divisions	discharged in	5 mins.
R. L. not acting	25	,,	,,	5 ,,
R. L. again acting and no screen	17	,,	,,	5 ,,

5.45.—Interior metal charged positively. Total charge 244.

R. L. in action and lead screen	1	scale division	discharged in	3 mins.
R. L. in action and no screen	6	,,	,,	3 ,,
R. L. not acting	0	,,	,,	3 ,,

Dec. 31, 1896. 10.54 a.m.—Interior metal charged positively. Total charge 163.

R. L. not acting	2	scale divisions	discharged in	3 mins.
R. L. acting & no screen	1	,,	,,	3 ,,

11.0—R. L. stopped ... 1·5 ,, ,, 2 ,,

R. L. again acting, no screen ... ... 3 ,, ,, ,,

R. L. stopped	2·5	,,	,,	,,

11.12.—Interior metal charged negatively. Total charge 342.

R. L. not acting... ...	10	scale divisions	discharged in	3 mins.
R. L. acting, no screen	21	,,	,,	3 ,,

11.18—R. L. stopped 11·5 ,, ,, 3 ,,

R. L. acting, no screen	16·5	,,	,,	3 ,,

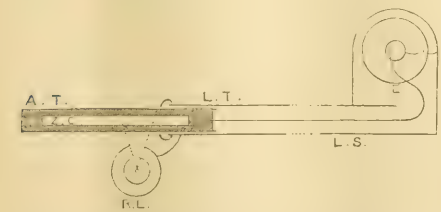

Fig. 1.—A. T., Aluminium tube; L. T. Lead tube; R. L., Röntgen lamp; L. S., Lead sheaths; E., Electrometer; ·, Paraffin; Z. C., Zinc cylinder.

These results are quite in accordance with those found in similar experiments by Röntgen; and they show that if paraffin is made conductive, it is only to so small an extent that it is scarcely perceptible by the method we have used.

To make a similar series of experiments with glass, we used a piece of glass tubing 9·5 mm. thick, length 70 cm., and 1 cm. external diameter. The inside of this tube was coated with a deposit of silver, which was placed in metallic connection with the insulated terminal of the electrometer. The outside of the glass was covered with wet blotting-paper connected to sheaths.

With this arrangement we obtained the following results:—

Feb. 8, 1897.

Insulated terminal of electrometer charged to − 333 scale divisions from the metallic zero.

4.23.—Röntgen lamp, acting ...	0·5	sc. div.	lost in	3 mins.
,, ,, not acting ...	1·0	,,	,,	5 ,,

Charged to + 164 scale divisions from the metallic zero.

4.36.—Röntgen lamp, not acting ...	13	sc. divs.	lost in	7 mins.
,, ,, acting ...	8·5	,,	,,	5 ,,
,, ,, not acting ...	6·0	,,	,,	6 ,,
,, ,, acting ...	3·5	,,	,,	5 ,,
,, ,, not acting ...	3·5	,,	,,	5 ,,

[Sensibility of electrometer, 140 scale divisions per volt.]

We next removed a part of the wet blotting-paper from the outside of the glass, and, after having charged the insulated interior metal deposited on the inside of the glass, we heated the exposed part with a spirit flame, in this way making the glass a conductor. Thus with a charge of + 280 scale divisions from the metallic zero, the loss in 30 seconds, during which time the glass was heated in the spirit flame, was 90 scale divisions; in the next minute, with no further heating, the loss was 20 scale divisions. Re-application of heat gave complete discharge in 2½ minutes. Thus we see that our method is amply sensitive to the conductance produced in glass by heating.

We conclude that the Röntgen rays do not produce any conductance perceptible in the mode of experimenting which we have hitherto followed.

A similarity in effects produced by flame and by Röntgen rays is brought out by the following experiments.

Two similar sticks of paraffin, which we shall call A and B respectively, each of about four sq. cm. cross section, were coated throughout half their lengths with tinfoil. These tinfoils ought to be each metallically connected to sheaths.

To obtain a sufficiently delicate test for their electric state, a metal disc of three cm. diameter was fixed horizontally to the insulated terminal of the electrometer.

The two pieces of paraffin were first diselectrified by being held separately in the flame of a spirit-lamp. Their non-tinfoiled ends were then pressed together, and their electric state again tested after separation. It was found that they were still free from electric charge. After this B was charged by being held over the pointed electrode of an inductive electric machine. The quantity of electricity given to it in this way was roughly measured by noting the electrometer reading when the paraffin was held at a distance of 4 cm. above the metal disc connected to the insulated terminal of the electrometer.

The free ends of A and B were again held together, and, after separation, both pieces were tested separately. The charged one, B, had suffered no appreciable loss, and the other, A, induced an electrometer reading of a few scale divisions in the same direction, when held as near as possible to the metal disc without touching it. This showed that an exceedingly minute quantity of electricity had passed from B to A when they were in contact.

A was then diselectrified by being held alone in the flame. The ends of A and B were again put together, and in this position were passed through the flame. They were tested with their ends still pressed together, and it was found that when held as near as possible to the metal disc without touching it, no reading was produced on the electrometer. After this they were separated and tested separately; and it was found that B, when held over the disc, gave a large reading in the same direction as before it had been passed through the flame, and A (which was previously non-electrified) gave a reading of about the same amount in the opposite direction.

The same results were obtained when Röntgen rays were substituted for the flame.

The explanation clearly is this: the flame or the Röntgen rays put the outer paraffin surfaces of A and B temporarily in conductive communication with the tinfoils; but left the end of B, pressed as it was against the end of A, with its charge undisturbed. This charge induced an equal quantity of the opposite electricity on the outer surfaces of the paraffin of A and B between the tinfoils; half on A, half on B.

When the application of flame or rays was stopped, this electrification of the outer paraffin surfaces became fixed. B, presented to the electrometer, showed the effect of the charge initially given to its end, and an induced opposite charge of half its amount on the sides between the end and the tinfoil. A showed on the electrometer only the effect of its half of the whole opposite charge induced on the sides by the charge on B's end.

We have here another proof that paraffin is not rendered largely conductive by the Röntgen rays. Had it been made so, then the charge given to the end would have leaked through the body of the paraffin to the outside, and have been carried away either by the tinfoil or by the conductive air surrounding the non-tinfoiled parts.

To show that the induced charges were fixed on the sides, the two sticks, A and B, were next coated with tinfoil throughout their whole length, only one end of each being uncovered. The uncoated end of B was then charged and pressed against that of A, and the two were held either in the flame of a spirit-lamp or in the Röntgen rays. When taken out of the flame or the Röntgen rays, and then separated and tested separately, it was found that B had retained its charge practically undiminished, and that A had acquired a very slight charge of the opposite kind.

Instead of placing the two ends of the paraffin in immediate contact, four pieces of metal of 1/10 of a mm. thickness were placed one at each corner of one of the ends, so that when the sticks of paraffin were placed end to end there was now an air space of 1/10 of a mm. between the paraffin ends. When B was charged and A not charged, and the two put end to end, and then exposed to flame or to Röntgen rays, it was found that B's end still retained its charge, and A's end acquired a very slight opposite charge.

With an air space of 1/5 of a mm. the same results were obtained.

With the air space increased to 1 mm. the charge on B was less after the two had been passed through the flame or the rays.

Similar experiments were made with rods of glass and of ebonite, with similar results.

FORTHCOMING BOOKS OF SCIENCE.

MR. EDWARD ARNOLD has in preparation:—Practical Science Manuals; Agricultural Chemistry, by T. S. Dymond; Steam Boilers, by George Halliday, illustrated; The Chemistry of the Raw Materials of the Coal-Tar Colours, by R. J. Friswell; A Manual of Physiology, by W. Snodgrass, arranged to meet the requirements of the syllabus of the Science and Art Department; The Calculus for Engineers, by Prof. John Perry; A New Elementary Geography, based on Frye's Complete Geography, and revised and largely re-written from the British standpoint, by Andrew J. Herbertson, illustrated.

Mr. Batsford announces:—A Text-Book on Sanitary Engineering, by C. E. Moore.

In Messrs. A. and C. Black's list are to be found:—Ferrets: their Management in Health and Disease, by Nicholas Everitt, illustrated; On the Threshold of Three Closed Lands, viz. Tibet, Nepal and Bhutan, by J. A. Graham.

Messrs. W. Blackwood and Sons give notice of:—Brown's Forester: a Practical Treatise on the Planting and Tending of Forest Trees and the General Management of Woodland Estates, edited by John Nisbet; Wild Traits in Tame Animals, being some Familiar Studies in Evolution, by Dr. Louis Robinson, illustrated; Man's Place in the Cosmos, and other Essays, by Prof. Andrew Seth; Prehistoric Problems, by Dr. R. Munro; Introductory Text-Book of Zoology, by Prof. H. Alleyne Nicholson, new edition, illustrated; Page's Introductory Text-Book of Geology, new edition, revised and enlarged by Prof. Lapworth.

Messrs. Cassell and Co., Ltd., will publish:—Cheap editions of The Story of the Sun, by Sir Robert S. Ball, illustrated; and Cassell's Concise Cyclopædia, illustrated; the completion of Cassell's Natural History, edited by P. Martin Duncan, three volumes, illustrated; a New Cyclopædia of Technical Education, six volumes, illustrated; new issues in serial form of The Story of our Planet, by Prof. T. G. Bonney, illustrated; and Familiar Wild Flowers, by F. E. Hulme.

In Messrs. J. and A. Churchill's list we find:—Commercial Organic Analysis, by Alfred H. Allen, vol. iii., part iv.; Practical Chemistry, by Prof. T. Campbell Brown; fourth edition; A System of Dental Surgery, by C. S. Tomes, third edition; A Short Practice of Midwifery, by Dr. Yellett; Bazaar Medicines, by Dr. Waring, fifth edition, revised by Dr. Aitchison; Fingers and Toes, by W. Anderson; Antiseptics for Nurses, by C. E. Richmond; Mechanical Dentistry, by T. Richardson, seventh edition.

The Clarendon Press has in preparation:—The Opus Majus of Roger Bacon, edited by J. H. Bridges, 2 vols.; The Flora of Berkshire, by G. C. Druce.

Mr. W. B. Clive promises:—A Manual of Psychology, by G. F. Stout; Questions on Welton's Logic, with illustrative examples, by H. Holman; Key to Holman's Questions on Welton's Logic; A Primer of Logic, by J. Welton; Advanced Algebra, by William Briggs and Prof. G. H. Bryan, based on the "Algebra" of Radhakrishnan; Euclid, Books I.–IV., by Rupert Deakin; Deductions in Euclid, by T. W. Edmondson and J. Briggs; Geometrical Conic Sections, by Prof. G. H. Bryan; Co-ordinate Geometry, by Prof. G. H. Bryan, part ii.; Mechanics of Fluids, First Stage, by F. Rosenberg; The Tutorial Dynamics, by William Briggs and Prof. G. H. Bryan; A Higher Text-Book of Dynamics, by Prof. G. H. Bryan; A Higher Text-Book of Hydrostatics, by Prof. G. H. Bryan; The Intermediate Trigonometry, by W. Briggs and Prof. G. H. Bryan; The Preceptors' Trigonometry, by W. Briggs and Prof. G. H. Bryan; The Properties of Matter, an Introduction to the Tutorial Physics, by E. Catchpool; Inorganic Chemistry, First Stage, by Dr. G. H. Bailey; Advanced Science and Art Chemistry, by the same author; A Synopsis of Non-Metallic (Inorganic) Chemistry, by William Briggs, fourth edition, revised by W. Hurtley; A Synopsis of Metallic Chemistry, by W. Hurtley; The Tutorial Chemistry, by Dr. G. H. Bailey, edited by William Briggs, part ii., Metals; Magnetism and Electricity, First Stage, by Dr. R. H. Jude; Advanced Science and Art Magnetism and Electricity, by Dr. R. W. Stewart; Sound, Light, and Heat, First Stage, by John Don; Advanced Science and Art Heat, by Dr. R. W. Stewart; Science and Art Physiography, by A. M. Davies.

Messrs. J. M. Dent and Co.'s list contains:—The First Crossing of Spitzbergen, by Sir Martin Conway, illustrated; Picturesque Burma, by Mrs. Ernest Hart, illustrated.

Mr. Heinemann will issue:—The New Africa: a Journey up the Chobé and down the Okovango Rivers, by Dr. A. Schulz and A. Hammar; Rhodesia, by Dr. F. Du Toit, illustrated.

Messrs. Hutchinson and Co. give notice of:—Concise Knowledge Library, illustrated: Vol. i. Natural History, by R. Lydekker, Dr. R. Bowdler Sharpe, W. F. Kirby, R. B. Woodward, F. A. Bather, W. Garstang, R. Kirkpatrick, and R. I. Pocock; vol. ii. Astronomy, by J. Ellard Gore, Agnes M. Clerke, and A. Fowler.

Messrs. Longmans' announcements include:—The Life and Times of Thomas Wakley, by S. Squire Sprigge; Papers and Notes on the Genesis and Matrix of the Diamond, by the late Prof. H. Carvill Lewis, edited from his unpublished MSS. by Prof. T. G. Bonney; Teaching and School Organisation, with especial reference to Secondary Instruction, edited by P. A. Barnett; Differential Equations, by D. A. Murray; A Guide to the Clinical Examination of the Blood for Diagnostic Purposes, by Dr. R. C. Cabot, illustrated.

Messrs. Sampson Low and Co., Ltd., will publish:—A Course of Elementary Experiments for Students of Practical Inorganic Chemistry, by Chapman Jones; How to Grow Begonias, by G. A. Farini, illustrated; Health and Condition in the Active and the Sedentary, by Dr. N. E. Yorke-Davies, fourth edition.

The announcements of Messrs. Macmillan and Co., Ltd., include:—Ancient Volcanoes of Britain, by Sir Archibald Geikie, 2 vols., illustrated; A System of Medicine, by many writers, edited by Dr. Thomas Clifford Allbutt: Vol. ii. containing Infections (continued); The Intoxications and the Parasites, also the General Diseases of Obscure Causation, such as Rheumatism, Gout, Diabetes, Rickets, Scurvy, &c.; Farm and Garden Insects, by Dr. William Somerville, illustrated; The Dahlia, by many writers; Infinitesimal Analysis, by Prof. William Benjamin Smith, Vol. i., Elementary; On Laboratory Arts, by Prof. Richard Threlfall; Mathematical Theory of Electricity and Magnetism, by A. G. Webster.

Messrs. Methuen and Co. promise:—British Central Africa, by Sir H. H. Johnston, illustrated; Scouting Sketches in Rhodesia, by Lieut.-Colonel Baden-Powell, illustrated; From Tonkin to India, by Prince Henri of Orleans, translated by Hamley Bent, illustrated; Three Years in Savage Africa, by Lionel Decle, illustrated; The Hill of the Graces: or, the Great Stone Temples of Tripoli, by H. S. Cowper, illustrated; The North-West Provinces of India, their Ethnology and Administration, by W. Crooke, illustrated; Neo-Malthusianism, by R. Ussher; Magnetism and Electricity, by R. Elliott Steel, illustrated.

In Mr. Murray's list we find:—Some Unrecognised Laws of Nature, an Inquiry into the Causes of Physical Phenomena, with special reference to Gravitation, by Ignatius Singer and Lewis H. Berens, illustrated; Zermatt and the Matterhorn, by Edward Whymper, illustrated; The Life of William Pengelly of Torquay, F.R.S., Geologist, with Selections from his Correspondence, by his daughter, Hester Pengelly, and a summary of his scientific works, by Prof. Bonney, illustrated; Waste and Repair in Modern Life, by Dr. Robson Roose; University Extension Manuals, edited by Prof. Knight; An Introduction to Physical Science, by Prof. John Cox; The History of Astronomy, by Arthur Berry; A History of Education, by Principal James Donaldson; An Introduction to Philosophy, by Prof. Knight.

Messrs. George Newnes, Ltd., have in preparation:—The Story of Animal Life, by B. Lindsay, illustrated; The Story of the Earth's Atmosphere, by Douglas Archibald, illustrated;

The Story of the Earth's Surface, by Prof. H. G. Seeley, illustrated; The Story of Religion, by E. D. Price, with map, &c.

Messrs. Kegan Paul, Trench, Trübner, and Co. Ltd., announce:—Studies in Psychical Research, by Frank Podmore; Creation with Development, by Captain J. D. K. Hewitt, with diagrams and an illustration; Fichte's Science of Ethics, translated by A. E. Kroeger, and edited by Prof. the Hon. W. T. Harris; new volume of "The International Scientific Series": What is Electricity? by Dr. John Trowbridge, illustrated; the "Agricultural Series": Chemistry, by R. H. Adie and T. B. Wood; Botany, by Dr Wm. Fream; Physiology and Feeding, by T. B. Wood and R. H. Adie; Agriculture, by Robert Menzies; Horticulture, by E. Pillow and W. K. Woodcock; The Conversion of Arable Land to Pasture, by Prof. W. J. Malden.

The Rebman Publishing Company, Ltd., will issue:—Yearbook of Medicine and Surgery, 1897, collected and arranged by eminent specialists and teachers, under the editorial charge of Dr. George M. Gould; The Diseases of Women: a handbook for students and practitioners of medicine, by J. Bland Sutton and Dr. Arthur E. Giles, illustrated; Injuries and Diseases of the Ear: being various papers on Otology, by Macleod Yearsley; Archives of Clinical Skiagraphy, by Sydney Rowland, part iv.

Messrs. L. Reeve and Co. have in the press:—Respiratory Proteids, by Dr. A. B. Griffiths.

Among the forthcoming books of the Scientific Press, Ltd., we notice:—The Romance and Mystery of Alchemy and Pharmacy, by C. J. S. Thompson, illustrated; Elementary Physiology for Nurses, by Dr. C. F. Marshall; "The Burdett Series" of popular Text-Books on Nursing: No. 1, Practical Hints on District Nursing, by Amy Hughes; No. 2, The Matron's Course: an introduction to hospital and private nursing, by S. E. Orme.

Messrs. Walter Scott, Ltd., will add to their "Contemporary Science Series":—Hallucinations and Illusions, by E. Parish; Psychology of the Emotions, by Ribot; The New Psychology, by Dr. E. W. Scripture; Man and Woman, by Havelock Ellis, second edition; Hypnotism, by Albert Moll, fourth edition.

The announcements of Messrs. Swan Sonnenschein and Co., Ltd., include:—Aristotle's Psychology, including the Parva Naturalia, translated and edited, with commentary and introduction, by Prof. William A. Hammond; Ethics, by Prof. W. Wundt, translated under the supervision of Prof. E. B. Titchener, 2 vols.; Physiological Psychology, by Prof. W. Wundt, translated by Prof. E. B. Titchener, 2 vols., illustrated; Introduction to the Study of Philosophy, by Prof. Oswald Külpe, translated by W. B. Pillsbury, under the supervision of Prof. E. B. Titchener; Text-Book of Palæontology for Zoological Students, by Theodore T. Groom, illustrated; Text-Book of Embryology: Invertebrates, by Drs. Korschelt and Heider, vol ii., Crustacea and Arachnoids, translated and edited (with additions) by Eric Pritchard; Practical Plant Physiology, by Prof. Wilhelm Detmer, translated by S. A. Moor; A Student's Text-Book of Zoology, by Adam Sedgwick, 2 vols., illustrated; Handbook to Practical Botany, for the botanical laboratory and private student, by Prof. E. Strasburger, edited by Prof. W. Hillhouse, new edition; The Young Beetle-Collector's Handbook, by Dr. E. Hofmann, translated and edited with an introduction by Dr. W. Egmont Kirby, illustrated; Organic Chemistry: Introduction to the Study of, by J. Wade; Among the Wild Flowers, by the Rev. H. Wood, vol. i. (Spring), vol. ii. (Summer); Fishes, by the Rev. H. A. Macpherson; Handbook of Grasses, by W. Hutchinson, illustrated; Mammalia, by the Rev. H. A. Macpherson; Birds' Eggs and Nests, by W. C. J. Ruskin Butterfield; The Dynamo: how made and how used, by S. R. Bottone, new edition, illustrated, and an appendix on the construction of a six-unit dynamo; Radiation, by H. H. F. Hyndman and Cecil H. Cribb, with an introduction by Prof. Silvanus P. Thompson; Williams' British Fossils, new edition; Specimens of Bushman Folk-lore, by Dr. W. H. J. Bleek and L. C. Lloyd, with a preface by Dr. George McCall Theal.

Mr. Fisher Unwin's list contains:—Glimpses into Plant Life, by Mrs. Brightwen, illustrated; Mother, Baby, and Nursery, a Manual for Mothers, by Mrs. Genevieve Tucker.

Messrs. Frederick Warne and Co. announce:—Wayside and Woodland Blossoms, by Edward Step, third edition; Favourite Flowers of Garden and Greenhouse, edited by E. Step, vols. ii. and iii.

Messrs. Whittaker and Co. announce:—Central Station Electricity Supply, by Gay and Yeaman; A Series of Electrica Engineering Designs, by Gisbert Kapp; Horseless Road Locomotion, by A. R. Sennett; A Railway Technical Vocabulary (French, English, and American), by Lucien Serraillier; A Technological Dictionary in Four Languages (English, French, Italian, and German); Loppé and Bouquet's Alternating Currents, a practical treatise, translated from the French by F. J. Moffett; The Alternating Current Circuit, by W. Perren Maycock; Railway Material Inspection, by G. R. Bodmer; Organic Chemical Manipulation, by J. T. Hewitt; Industrial Electro-Chemistry, by Dr. Hoepfner; Whittaker's Engineers' Pocket-Book; Practical Electrical Measurements, by E. H. Crapper; Vol. ii. of Electric Lighting and Power Distribution, by W. Perren Maycock; A School Geography, by C. Bird.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The degreee of D.C.L., *honoris causa*, will be conferred on Dr. Nansen to-day, March 18, in the Sheldonian Theatre at 3 p.m.

Dr. James Ritchie has been appointed Lecturer in Pathology for two years, from January 1, 1897.

The bust of Sir Henry Acland, Bart., K.C.B., formerly Regius Professor of Medicine, has been placed in the Court of the University Museum.

The Romanes Lecture will be delivered on Wednesday, June 2, 1897, by the Right Hon. John Morley, M.P., D.C.L. The subject will be Machiavelli.

The Junior Scientific Club held its last meeting on Friday, March 12, Mr. A. W. Brown (Ch. Ch.), President, in the chair. Mr. E. H. Hunt (Balliol) gave an account of some experiments made by himself on the "Excretion of Urea and Phosphates." Mr. W. B. Billinghurst (St. John's) read a paper on "Pentacarbon Rings," and Mr. J. N. Ramsden (New Coll.) on "Coal in Kent." The following were elected Members of Committee for next term:—Mr. R. A. Buddicom, Keble (President), Mr. J. E. H. Sawyer, Ch. Ch., Mr. A. Hartridge, Exeter (Secretaries), Mr. A. E. Boycott, Oriel (Treasurer), Mr. A. R. Wilson, Wadham (Editor), and Messrs. W. B. Billinghurst, St. John's, N. B. Odgers, Lincoln, and W. M. G. Glanville, Ch. Ch.

CAMBRIDGE.—THE following is the speech delivered by the Public Orator, Dr. Sandys, Fellow and Tutor of St. John's, in presenting Dr. Nansen for the honorary degree of Doctor in Science, on March 16:—

Scandinaviae filium intrepidum, oceani septentrionalis exploratorem indefessum, post tot pericula terra marique per tres annos fortiter tolerata, salvum et sospitem reducem salutamus. Quid referam viri indomiti iuventutem primam disciplina severa assidue exercitam, et rerum naturae studiis feliciter dedicatam? Quid itinera per priora animi et corporis patientiam et fortitudinem spectatam probatamque? Quid itinere in ultimo, adiutoris optimi auxilio, tot observationes sive magneticas sive meteorologicas e regione prius ignota reportatas? Quid dicam de bene ominati nominis nave illa, quae glaciei solidae in mediis molibus, velut Symplegadum novarum in amplexu, constricta et compressa, ductoris tamen providi vota non fefellit, sed, mobili in glacie immobilis inhaerens, ad ulteriora sensim delata est? Navam illam, navisque rectorem, ipsum Vergilium praedixesse crediderim:—

> "alter erit tum Tiphys et altera quae vehat Argo
> delectos heroas."

Quis autem pro rei dignitate laudare poterit par nobile illud comitum, qui, nave ipsa relicta, glaciei asperrimae per solitudines immensas audacter progressi, in regionem tandem pervenerunt orbis terrarum vertici septentrionali proximam, quo ex ipsa mundi origine nulla hominum vestigia prius umquam penetraverant? Etiam arctoi pelagi tum demum patefacti de navita primo Horati verba licet usurpare:

> "illi robur et aes triplex
> circa pectus erat qui fragilem truci
> commisit pelago ratem."

Talium virorum exemplo admoniti discimus nihil magnum, nihil memorabile, nisi labore longo curaque infinita posse perfici. Talium virorum in orbe terrarum explorando providentia et

fortitudine verba poetae Romani futura vaticinantis denuo vera reddita sunt :—

"venient annis saecula seris
quibus oceanus vincula rerum
laxet et ingens pateat tellus,
Tethysque novos detegat orbes
nec sit terris ultima Thule."

The following is the speech delivered by the Public Orator, Dr. Sandys, on March 11, in presenting Prof. Felix Klein, of Göttingen, for the honorary degree of Doctor in Science :—

Universitatem Goettingensem nostis omnes a rege nostro Hanoveriensi, Georgio secundo, fuisse fundatam. Eo maiore gaudio scientiae mathematicae professorem Goettingensem, Newtoni Universitatis nomine, salutamus, virum vinculo non uno nobiscum coniunctum, non modo societatis regiae et societatis philosophicae Cantabrigiensis inter socios exteros numeratum, sed etiam a societate mathematica Londinensi exteros inter omnes numismate honorifico solum donatum. Nuper Newtoni nostri a linearum tertii ordinis enumeratione exorsus, et lineae curvatae et superficies rationibus Algebraicis expressae quam potissimum formam revera habere demonstratae sint, luculenter enarravit ; idem Caleii nostri inventa insignia in maius auxit et rebus novis explicandis feliciter adhibuit. Neque Europae tantum terminis inclusus, etiam inter fratres nostros transmarinos, scientae suae provincia tota colloquio familiari breviter percursa, inter alia ostendit scientiae illius regionem puram (ut aiunt) a scientia eadem ad usum cotidianum adhibita non sine periculo posse divelli ; ne numerorum quidem *θεωρίαν*, quam gloriatum esse quendam utilitatis macula nondum esse inquinatam, solam per se posse separari. Ergo scientiae mathematicae partes omnes societate quadem inter se coniunctas esse libenter accipimus ; neque minus libenter confitemur hodie non modo omnes doctrinae sedes, sed etiam gentes omnes, ubi doctrina in honore est, necessitudinis vinculis artissimis inter sese esse consociatas.

Dr. Arthur Willey has been re-elected Balfour student for one year.

The Vice-Chancellor has appointed Prof. A. W. Rücker, secretary of the Royal Society, to the office of Sir Robert Reade's lecturer.

MR. J. T. CUNNINGHAM has been appointed lecturer on fisheries under the Cornwall County Council Technical Instruction Committee.

IT is reported that, in addition to the offer of 5000*l.* towards the foundation of a chair of public health in the University of Edinburgh, a further offer of 3000*l.* towards the same object had been received from the same donor.

FROM a reply made by the First Lord of the Treasury to a question asked by Sir H. Havelock-Allan, in the House of Commons on Tuesday, it seems that the Government have no great hope of being able to deal with secondary education in the course of the present Session. Secondary education is thus postponed *sine die*.

MR. JAMES R. PARSONS, JUN., Director of Examinations of the Board of Regents of the University of the State of New York, has made his annual report. He notes an extraordinary development in the condition of medical schools within the last four years, notwithstanding that the standards for admission and the courses of instruction have been greatly raised. In 1893 the total value of property was 2,108,855 dols., which has now increased to 4,562,836 dols. The receipts were 262,129 dols., and they have increased to 498,146 dols. In 1895 there were 22,887 medical students in the United States, of which number about 17 per cent. were in the State of New York.

THE excellent courses of study followed at the Central Technical College and the Finsbury Technical College are too well known to need commendation. At the former institution advanced instruction is provided in those kinds of knowledge which bear upon the different branches of productive industry ; and at the latter a systematic scheme of technical education, suitable for students who will fill intermediate posts, may be followed in day classes, or special subjects may be taken up in evening classes. The programmes of both Colleges have just been issued by the City and Guilds Institute, and a reference to them will show what valuable work the Colleges are doing for the advancement of science and industry.

WE are glad that Prof. Warington's appeal for a further recognition of agricultural teaching at Oxford, referred to in last week's NATURE (p. 449), has been given support by the Clothworkers' Company. The Company has communicated to Prof. Warington the following resolution :—"That a sum of 200*l.* per annum be guaranteed by the court for five years, for the purpose of enabling the Sibthorpian Professor of Rural Economy at Oxford to supplement his lectures by those of specialists, embracing the most important parts of agriculture and forestry ; it being understood and stipulated, however, that no part of the sum so guaranteed is to be drawn in the event of the University not consenting to make agriculture a subject in the Pass School." It is remarked that if this action of the Company promotes the desirable object of inducing the (Oxford) University to bring agriculture and the sciences ancillary thereto into the curriculum of the University and of impressing it with the sanction of a degree as at the Scotch Universities, the Company will be gratified to have contributed to some extent towards a consummation so devoutly to be wished for.

SCIENTIFIC SERIALS.

American Journal of Science, March.—Crater Lake, Oregon, by J. S. Diller. (See p. 470.) The little-known crater lake of Southern Oregon is remarkable not only for its geological history, but also on account of its position and depth, its beautiful blue transparent waters, and the grandeur of its completely encircling cliffs, which afford no outlet. The rim of the lake, which is nearly circular, with an average diameter of six miles, rises 1000 feet above the general level of the Cascade range. During the glacial period the site of the lake was occupied by a huge volcano. The rim is not made up of fragments, but of solid lava, alternating with conglomerate and tuff. The lake basin is therefore probably not due to eruption, but to subsidence.—Outline of a natural classification of the Trilobites, by C. E. Beecher (Part ii.). This important paper gives a classification of the Trilobites on the principles detailed in the first part. The sub-class Trilobita is divided into three orders, viz. Hypoparia, three families ; Opisthoparia, seven families ; Proparia, four families. Complete diagnoses are appended, the chief characteristics being : Hypoparia, free cheeks, forming a continuous marginal ventral plate of the cephalon, and in some forms also extending over the dorsal side at the genal angles. Opisthoparia : free cheeks, generally separate, always bearing the genal angles. Proparia : free cheeks not bearing the genal angles. These orders are in chronological succession, the Hypoparia being the smallest and oldest, and the Proparia only beginning in the Ordovician.—Excursions of a telephone diaphragm, by C. Barus. Experiments with a Michelson refractometer and a mirror attached to a telephone diaphragm prove that the excursions corresponding to sounds of faint but distinct audibility are small as compared with the wave-length of sodium light. They are probably below 10^{-6} cm. The force necessary to produce this flexure exceeds 10 dynes in a plate 2 cm. in radius and 0·016 cm. thick.—The Arctic Sea ice as a geological agent, by R. S. Tarr. The sea-made ice protects the coasts from sea-erosion until it breaks up and forms a kind of grinding tool and carrier of débris. In some regions of floe ice along the Labrador coast fully 50 per cent. of the floes are discoloured by detritus.—Iodometric estimation of molybdenum, by F. A. Gooch. In reducing molybdic acid by means of hydriodic acid, the development of the green colour is not a sufficient criterion of the exact reduction to the pentoxide and of the removal of the iodine, which should be theoretically set free. It is better to boil down the liquid by a certain amount in an apparatus so arranged that a current of pure CO_2 can be passed through retort and receiver during distillation. This avoids the action of the air upon the hot vaporous hydriodic acid in the retort.

Bollettino della Società Sismologica Italiana, vol. ii. N. 5, 6. —L. Palmieri, a brief notice of his life and work.—On the variation of the velocity of seismic waves with the distance, by G. Agamennone.—Horizontal pendulums for continuous mechanical registration, by G. Grablovitz.—Note on the Tōkiō earthquake of June 20, 1894, by F. Omori.—On the intensity and amplitude of the movement in the great Japanese earthquake of October 28, 1891, by F. Omori.—Notices of earthquakes registered in Italy (June to August 1896), the more important being a valuable series of records of the earthquake of June 15, which gave rise to the great sea-waves in Japan, and several records of the shocks which occurred in Iceland on August 27.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 4.—"Experiments on the Absence of Mechanical Connection between Ether and Matter." By Oliver Lodge, D.Sc., F.R.S., Professor of Physics, University College, Liverpool. Received January 19.

The author gives an abbreviated account of a long series of experiments conducted by himself and his assistant, Mr. Davies, in continuation of those related in *Phil. Trans.*, 1893 (Aberration Problems, &c.). The method consists in bifurcating a beam of light, and sending each half in opposite directions round a closed periphery very near a rapidly rotating mass of matter, and then observing by means of interference fringes whether the velocity of light is affected in the slightest degree by this neighbourhood of moving matter. The steel disks have been now whirled to higher speeds, chiefly at 3000 revolutions a minute; the steadiness of the machine and the definition of the bands have been improved, other minor improvements have been made, and a long series of micrometric readings have been taken, both at increasing and at decreasing speeds.

Further, the steel disks have been replaced by a much more massive lump of iron, weighing ¾ ton, with a narrower channel for the light to travel in; and the bands have been observed close up to the moving surface, and even when reflected in it. The rotation was also continued for some hours to see if by chance *time* had any influence.

Moreover, the iron mass was strongly magnetised by a steady current, so that the light travelled across a moving magnetic field; and lastly the steel disks were replaced, with an insulated third disk between them, and strongly electrified, so that the beam of light travelled across a moving electrostatic field. After a number of spurious disturbances had been gradually eliminated, the author finds that in none of these ways is the velocity of light at all appreciably affected, and accordingly concludes that there is no viscous connection between the ether and matter of observable magnitude; *i.e.* that whatever motion moving matter may confer upon the ether must be of an irrotational kind. It was demonstrated theoretically in the previous memoir that no optical experiments could be competent to detect motion of this latter character, and accordingly no attempt has been made to look for any kind of motion except such as would be caused by something akin to viscosity.

Incidentally the author points out that by rotating the whole optical apparatus and observer, instead of the disks, at a very moderate speed, a shift of the bands should be seen; and even that the earth's rotation would with a large enough frame produce an effect, which latter, however, it appears difficult or impossible to observe, not on account of its smallness, but on account of its constancy.

The effect to be expected on Fresnel-Fizeau principles from whirling *air*, was unfortunately just too small for the author to safely observe. The residual disturbing causes just masked it, but it is probably not beyond the reach of another attempt with a still more thoroughly steady machine, if any one feels inclined to persevere so far. At the same time if it be supposed that any microscopic trace of true ether effect still possibly exists (which the author wholly disbelieves), and if a further attempt be hereafter made to observe it, a number of slight residual disturbing causes would be got rid of (and probably other difficulties introduced), by rotating the machine in a vacuum.

Physical Society, March 12.—Mr. Shelford Bidwell, President, in the chair.—Mr. William Barlow read a paper on a mechanical cause of homogeneity of structure and symmetry, geometrically investigated, with special application to crystals and to chemical combination, illustrated by models. The author has previously established that every homogeneous structure displays one or other of the thirty-two kinds of crystalline symmetry. He now shows that homogeneous structures possessing most, if not all, of these kinds of symmetry may be produced mechanically, as the equilibrium arrangements of assemblages of mutually-repellent particles; and also that these mechanical systems of particles exhibit characteristics entirely analogous to certain crystalline and other properties of matter. The fundamental concept may be summarised thus: A number of different kinds of mutually-repellent particles dispersed through space; the amount of this repulsion being some inverse function of the distance between the particles concerned; the particles are destitute of polarity, and the difference in kind consists in a difference in the degree of mutual repulsion which two particles exercise, according to the kinds taken. It is further premised that the assemblage is agitated so as to render unstable all but the final equilibrium arrangement, and a means is provided for linking the particles symmetrically, and unlinking them, under certain circumstances, so as to modify the repulsion between the particles affected. The data thus summarised may be regarded as merely provisional, because the making of the equilibrium arrangement one in which "closest packing" prevails is the object primarily aimed at; and these concepts are mere devices for attaining this end. By the employment of particles of different kinds, a large amount of variety is provided for. The first step taken is to deduce the law of "closest packing," which runs thus: Every assemblage of mutually-repellent particles will continually approximate to, or strive after, that relative arrangement of the particles composing it, in which it has come, at every part, to occupy a minimum of space under a given general pressure, or average repulsion, between the particles. This law acts on all assemblages, of the nature defined, however numerous the kinds of particles composing them; but, for its effects to be traceable, a very limited number of kinds must be present. Passing from assemblages consisting of a single kind of particle, the author takes a very simple case of two kinds of particles confined to a plane, and shows what type of symmetry will be produced when equilibrium is realised. Very simple cases of particles in space are then taken, and it is shown that a large number of different kinds of symmetry are displayed by the equilibrium arrangements produced when there is variety in the relations between the repulsions. To illustrate "close packing," stacks of balls of various sizes are employed; but it is pointed out that the conditions of statical equilibrium of the particles are not always adequately expressed in this way, although every case of the latter kind can be represented approximately by a case of the former kind, possessed of the same order of symmetry. Very slight variation in the relations between the repulsions, alters the form of the equilibrium arrangement; sometimes merely changing the angle without affecting the type; sometimes, when it passes some critical point, bringing about an alteration in type. Changes of the first kind resemble the change in crystal form caused by variation of temperature, whilst those of the latter kind, especially when associated with rearrangement of the particles, are analogous to polymorphism. In many cases, the arrangement of the particles is such that some may be removed without affecting the distribution of the remainder, and without disturbing the "close packing"; if, therefore, other particles, exercising a slightly less repulsion, be substituted for the removed, *inoperative*, particles, the only resulting change consists in a diminution of the pressure on the particles surrounding them. A species of isomorphism is in this way realised. When the particles of an assemblage are partially connected by hypothetic linking in a symmetrical manner, similar groups are formed; but, in order that the formation of such groups may not be arbitrary, the partitioning which is produced must have as complete symmetry as that of the partitioned structure. In consequence of this, some kinds of groups are not directly obtainable by symmetrical partitioning of a homogeneous structure; but it is always conceivable that they may be included in the larger groups of some more complex constellation, and that they may be subsequently separated to form an assemblage by themselves. Consequently, very intricate results may be reached by successive steps; symmetrical intermixture, linking, and unlinking, succeeding one another until complicated groups are built up, for the production of which such an agency as "close packing" appears at first sight inadequate. Having called attention to a large number of arrangements, some capable and some incapable of symmetrical partitioning into groups of a single kind, some linked and some unlinked, the author contends to have established the following two propositions: (1) The nature of the symmetry displayed by a homogeneous assemblage of mutually-repellent particles of different kinds, in equilibrium, depends on the relations subsisting between the repulsions exercised by these particles. (2) The assemblages belonging to all of the thirty-two classes of crystalline symmetry, result from the fundamental law of "close packing," when the relations between the different repulsions take the widest possible range of variety. Links which restrain the action of the repulsions can be present between some of the particles in some cases. The author refers to crystal "twinning," and points out that the action of dimorphism is competent to produce analogous "twinning" of symmetrical

assemblages of linked particles. A number of other properties of linked assemblages analogous to those of crystals are also described. In the domain of chemistry the author cites the continually accumulating experimental evidence of the existence of geometrical arrangement in the molecule, both that established stereochemically and that derived from the study of isomerism, as revealing a state of things precisely such as is arrived at by the law of "closest packing" in assemblages afterwards broken up into similar groups of particles. Attention is called to many groupings of the latter order fulfilling very exactly the conditions of disubstitution in the case of many carbon compounds. While he does not regard his work as throwing any light on the nature of change of state, or change of bulk, the author observes that the distribution in precise proportions of the constituents, which must obviously accompany or precede a chemical combination, may fairly be claimed as a resemblance to the regular intermixture brought about according to the law of "closest packing." He further suggests that the reason why some bodies do not readily interact may be due to the "close packing" of one or both. Prof. Herschel said he was particularly pleased with the models. He thought it probable that a very wide application would be found for the author's results. There was, no doubt, much to be learnt from models built up of spheres of two or more sizes, but it would be necessary to learn a great deal more about these symmetrical arrangements before they could be applied with any degree of certainty. Mr. Fletcher said it was impossible to criticise the paper without long and careful study. From certain hypotheses the author had deduced a law of "closest packing" that seemed adequate to explain many results observed by chemists and crystallographers; at the same time admitting that the law might be presumed from other reasoning. By his models he had tried to present a picture not of the forms of atoms or molecules, but merely analytical representations of the probable structure of particles. Hitherto, the research had been confined to determining the possible arrangements of particles all of one kind, but here were examples of packed spheres of various sizes. It was not quite clear how, in an elementary substance, there could be such a structure, although there certainly were cases of polymorphism awaiting explanation, as for instance with sulphur. The paper with its 188 pages of MS. represented a vast amount of clear thinking, and many years of admirable work. Prof. Adams called the attention of Fellows of the Physical Society to the museum at King's College, where were the original models as made and used by the early investigators of this branch of physics. Prof. Miers (communicated, too late for reading). The principle of "close packing" was not new, but Mr. Barlow was the first to extend it to explain solution, diffusion, and stereochemical problems. His remarks on the growth of curved crystals, vicinal faces, and pseudo-symmetrical crystals, were open to criticism. With regard to vicinal faces, however, lencite seemed to be a mineral in accord with his hypothesis. The author regarded a crystal as consisting of mutually repellent particles of different sorts; this seemed a very right way of attacking the problem of crystal structure, and would explain some recent observations of Rinne on crystals consisting of water particles and silicate particles. Further, Mr. Barlow had considered the way in which an assemblage might be broken up by the loosening of the ties, and the change of partners, among individual members. That is to say, he had considered crystallisation and solution; features quite ignored by ordinary theories. His view of crystal structure failed to explain why crystals should have faces, and gave no hint as to the controlling forces which keep mutually-repellent particles together. Nevertheless it suggested, among other striking analogies, those bearing on the relationship between crystal structure and chemical constitution; and the irregularities of crystals, such as were commonly neglected in accepted theories. Mr. Barlow had opened up a very promising line of inquiry. Mr. Barlow, in replying, said he greatly appreciated the interest shown in his work.—The President then proposed a vote of thanks to the author, and the meeting was adjourned until March 26. At the invitation of Dr. S. P. Thompson, the Society will on that occasion meet at the Technical College, Leonard-street, Finsbury.

Chemical Society, February 18.—Mr. A. G. Vernon Harcourt, President, in the chair.—The Longstaff medal of the Society was awarded to Prof. Ramsay.—The following papers were read:—The formation of dithionic acid in the oxidation of sulphurous acid by potassium permanganate, by T. S. Dymond nd F. Hughes. In oxidising sulphurous acid by potassium permanganate the authors find that, in addition to sulphuric acid, a constant proportion of dithionic acid is produced; an explanation of this fact is suggested.—On the production of pyridine derivatives from ethylic β-amidocrotonate, by J. N. Collie. Ethylic β-amidocrotonate hydrochloride condenses on heating to give the ether of an oxylutidine $C_{10}H_{13}NO_3$; an isomeric ether is obtained on heating a mixture of the amidocrotonate and its hydrochloride. The corresponding acids decompose on heating, yielding pseudolutidostyril.—Sodamide and some of its substitution derivatives, by A. W. Titherley. Sodamide yields substitution derivatives with amines or amides of the composition NaNHR or NaNH.CO.R respectively.—Rubidamide, by A. W. Titherley. Rubidamide, or $RbNH_2$, is obtained by heating rubidium in ammonia; it is crystalline, melts at 285–287°, and is decomposed by water or alcohol.—On the spectrographic analysis of some commercial samples of metals, of chemical preparations, and of minerals from Stassfurt potash beds, by W. N. Hartley and H. Ramage. The spectroscopic examination of a large number of materials has enabled the authors, in continuation of their previous work, again to demonstrate the wide distribution of many of the rare metals.—Dissociation pressure of alkylammonium hydrosulphides, by J. Walker and J. S. Lumsden.—Supposed condensation of benzil with ethyl alcohol. A correction, by F. R. Japp.—The viscosity of mixtures of miscible liquids, by T. E. Thorpe and J. W. Rodger. The authors contribute the results of measurements made on mixtures of carbon tetrachloride and benzene, methyl iodide and carbon bisulphide, and of ether and chloroform. The densities of the mixtures cannot be calculated by the ordinary admixture rule, whilst the viscosity is rarely a linear function of the composition.—Magnesium nitride as a reagent, by H. L. Snape. The author has investigated the action of magnesium nitride on chloroform, perchlorethane and benzaldehyde, in the hope of obtaining hydrogen cyanide, cyanogen and $(C_6H_5.CH)_3N_2$ respectively; the experiments, however, were unsuccessful.—The identity of Laurent's amarone with tetraphenylazine, by H. L. Snape and A. Brooke. Tetraphenylazine is obtained by the action of magnesium nitride on benzaldehyde; it is identical with Laurent's amarone.—Studies on the interaction of highly purified gases in presence of catalytic agents, by W. French. In absence of light spongy platinum does not induce combination in a mixture of dry hydrogen and oxygen.—Contributions to the knowledge of the β-ketonic acids. Part iii., by S. Ruhemann.—Contributions to the knowledge of the β-ketonic acids. Part iv., by S. Ruhemann and A. S. Hemmy.—Oxidation of phenylstyrenyloxytriazole, by G. Young. Phenylstyrenyloxytriazole is oxidised by permanganate to phenyloxytriazolecarboxylic acid, which immediately decomposes, yielding phenyloxytriazole  —Apiin and apigenin (preliminary notice), by A. G. Perkin. Apigenin $C_{15}H_{10}O_5$, the product of hydrolysis of apiin, the glucoside of parsley, contains no methoxy-groups, and yields a tribenzoyl-compound.—Note on the constitution of the so-called "nitrogen iodide," by J. W. Mallet.

Geological Society, February 24.—Dr. Henry Hicks, F.R.S., President, in the chair.—On the nature and origin of the Rauenthal serpentine, by Miss Catherine A. Raisin. This serpentine has been already described by Herr Weigand as one of those which occur in regions of gneiss or schist related in their origin to these rocks. In order to test this hypothesis as to the formation of the serpentine, the author examined the district and studied its rocks with the microscope. Herr Weigand asserted that transitions could be recognised from typical gneiss to a peculiar amphibolite, and that the latter rock had been changed to serpentine. The author could find in the field no evidence of a passage from gneiss to amphibolite, and called attention to the general difficulty of the supposition.—On two boulders of granite from the middle chalk of Betchworth (Surrey), by W. P. D. Stebbing. The author noticed cases of occurrence of boulders in chalk which have been previously described; and recorded the occurrence of two boulders which were obtained from the chalk of the *Terebratulina-gracilis* zone. The largest weighed 7 lb. 7 oz., measured 5″·8 × 6″·25 × 4″·125, and consisted of decomposed granite; valves of *Spondylus latus* and *Serpula* were still attached. The other, also granite, though of a different character, weighed 3 lb. 12 oz., and measured 3″·6 × 5″·8 × 4″·5. Prof. Bonney furnished a description of the microscopic characters of the two boulders, which are possibly

of Scandinavian origin. The author discussed the mode of transport to their present position, and favoured the agency of floating ice.—Coal: a new explanation of its formation; or the phenomena of a new fossil plant considered with reference to the origin, composition, and formation of coal-beds, by W. S. Gresley. The author argued that the brilliant black laminæ in coal and similar materials to those that form these laminæ, which are found in earthy coals, shales, and clays, point to the former existence of an aquatic plant, having the general shape of the modern *Platycerium alcicorne*, which grow *in situ*. He believed that much coal was formed by this aquatic "coal-plant," which grew amongst the mechanical sediments and the débris of the terrestrial vegetation that accumulated on the floors of sheets of water.

Zoological Society, March 2.—Dr. W. T. Blanford, F.R.S., in the chair.—The Secretary exhibited two specimens of a new viper, recently discovered by Captain A. H. McMahon during the recent survey of the Indo-Persian frontier, and named *Eristicophis macmahoni* (gen. et sp. nov.) by Dr. Alcock. This snake had been met with only in the sandy portions of the desert between Mushki and Persia, where it was almost impossible to detect its presence, owing to its habit of lying buried in the sand with only its head visible.—Mr. Gambier Bolton gave an account (illustrated by photographs shown by the oxy-hydrogen light) of a recent visit that he had made to the Bird Islands in Saldanha Bay, South Africa. The photographs illustrated the life of the black-footed penguin (*Spheniscus demersus*) on these islands, showing these birds in groups, nest-building, sitting on their eggs, and moulting. Mr. Bolton also gave an account of the guano- and egg-industry carried on by the Cape Government in the Bird Islands and other adjacent islands.—Mr. W. B. Tegetmeier exhibited and made remarks upon a specimen of a starling (*Sturnus vulgaris*) with enormously elongated mandibles.—Mr. H. M. Wallis read a paper entitled "The Growth of Hair upon the Human Ear, and its testimony to the Shape, Size, and Position of the Ancestral Organ."

Entomological Society, March 3.—Mr. R. Trimen, F.R.S., President, in the chair,—Mr. George W. Bird, Mr. Alfred H. Martineau, Mr. Hubert C. Phillips, Mr. William A. Vice, and Mr. Colbran J. Wainwright were elected Fellows of the Society.—Mr. Champion exhibited, on behalf of Messrs. Godman and Salvin, a portion of the Elateridæ, and the Cebrionidæ and Rhipidoceridæ recently worked out by him in the "Biologia Centrali-Americana." The Elateridæ included 531, the Cebrionidæ 29, and the Rhipidoceridæ 14 species, a large proportion of which were described as new. He called attention to the excessive rarity of the males in the Elaterid genera *Chalcolepidius* and *Semiotus* (the contrary being the case in the genus *Scaptolenus* of the Cebrionidæ, and also in many Elateridæ). One species, *Meristhus scobinula*, Cand., was common to Central America and China.—Mr. Jacoby showed a Halticid beetle, taken in Mashonaland by Mr. G. A. K. Marshall, and remarkable for a prolongation of the hind tibia beyond the tarsal articulation into a very long serrated process.—Mr. Elwes showed a series of Papilionidæ of the *Machaon* group, from North America, including *P. machaon* and *P. oregonia* from British Columbia, *P. brucei*, *P. bairdii*, and *P. zolicaon* from Glenwood Springs, Colorado, and the latter species from British Columbia. He stated that there was a tolerably complete gradation from *P. oregonia* (= *machaon*) through *P. brucei* to *P. zolicaon*, that none of the characters which had been relied on for separation were of real value, and that the structure of the genitalia afforded no assistance.—Mr. O. H. Latter read a paper on "The prothoracic gland of *Dicranura vinula*, and other notes," in continuation of his previous communications on the subject. A fresh use of the formic acid secreted by the larva was described; it was employed to alter the silk secreted in spinning the cocoon, in order to convert it into the well-known horny mass. If the acid was prevented from acting, as by supplying the larvæ with bits of blotting-paper soaked in an alkali to be utilised in making the cocoon, the silk thus protected from the action of the acid retained its usual fibrous structure.—Sir George Hampson communicated a paper on "The Classification of two subfamilies of Moths of the Family Pyralidæ—the *Hydrocampinæ* and *Scopariane*."

CAMBRIDGE.

Philosophical Society, February 22.—Mr. F. Darwin, President, in the chair.—On the diffraction pattern near the focus of a telescope, by Mr. R. H. D. Mayall. The diffraction pattern dealt with in this paper is supposed to be formed by the light from a star, upon a screen placed near the focus of a telescope. Series have been given by Lommel for the calculation of the intensity of illumination at any point of the pattern, but these become useless when the screen is more than a millimetre distant from the focus of a telescope of ordinary aperture. The series may, however, be transformed into a shape from which approximate values of the intensity may be found. This is shown in the present paper. It appears from the results that the pattern consists of a bright and comparatively broad ring surrounding a series of fainter and narrower rings, these latter fading away rapidly into a uniformly illuminated space. Further inwards towards the centre the uniform illumination disappears and another series of rings is formed.—On the marks made by stars on photographic plates exposed near the focus of a telescope, by Mr. H. F. Newall. In this paper an account is given of some of the appearances presented by photographs of star images taken near the focus of a telescope, with special reference to the concentration of light near the boundaries of the images when the aperture of the telescope is partly obstructed. The observations recorded are in the main supplementary to those which were published in the *Monthly Notices* of the Royal Astronomical Society in 1894 and suggested the theoretical investigation undertaken by Mr. Mayall.—Theorems on the contacts of spheres, by Mr. W. McF. Orr.—Change of the independent variable in a differential coefficient, by Mr. E. G. Gallop.—On a method of Lie for solving partial differential equations, by Dr. A. C. Dixon.

PARIS.

Academy of Sciences, March 8.—M. A. Chatin in the chair.—Researches on the earths contained in the monazite sands, by MM. Schutzenberger and Boudouard.—The sulphate of cerium obtained from monazite sand gave numbers on analysis indicating an atomic weight sensibly higher than the cerium sulphate obtained from cerite. It was found possible to break up the former into three fractions, one not precipitated from solution by cupric oxide, with an atomic weight of 138, another precipitated from the solution of its sulphate by both cupric oxide and by sodium sulphate (atomic weight about 148), and the third precipitated by cupric oxide, but not by sodium sulphate (atomic weight about 157).—On the apparatus employed to collect samples of air at a great height, in the ascent of the *Aérophile* on February 18, 1897. Analysis of the air collected, by M. L. Cailletet. The vacuous reservoir was fitted with a special tap, worked by a clock, so arranged as to open at one hour and a quarter after commencing the ascent, previous experiments having shown that this corresponded with the maximum height. The results of the analysis showed that the composition of the air at these high altitudes (51,000 feet) is practically the same as on the ground. Observations on the subject of the preceding communication, by M. A. Müntz. The slight diminution in the oxygen found, and the slight increase in the carbonic acid, may possibly be due to a slight oxidation of the grease used to lubricate the tap.—M. G. Bonnier was elected a member in the Section of Botany, in the place of the late M. Trécul.—On the reduction of the general problem of integration, by M. Riquier.—Theorem on entire series, by M. Hadamard.—On the centres of gravity of surfaces parallel to a closed surface, by M. Ernest Duporcq.—On permanent deformation of glass, and displacements of the zero of thermometers, by M. L. Marchis. Experiments are cited showing that alternate heating and cooling of a thermometer is more efficacious in displacing the zero of a thermometer than long heating at a fixed temperature.—Application of the Röntgen rays to measure the electromotive force of contact, by M. Jean Perrin.—The action of phosphorus upon gold, by M. A. Granger. At a temperature of about 400° C. phosphorus vapour combines with gold, forming a phosphide, Au_3P_4. To isolate this it is necessary to cool the tube rapidly, as the temperature limits between which the compound is stable are very narrow.—On the estimation of antimony in the state of peroxide, by M. H. Baubigny. Sb_2O_5 is fairly stable at 357°, begins to lose oxygen at 440°, and leaves a constant residue of Sb_2O_4 at 800°, the purity of which was tested by dissolving in hydrochloric acid in presence of potassium iodide, and weighing the antimony as the trisulphide.—Action of free bases on salts, by M. Albert Colson. From an experimental study of the replacement of diisobutylamine and piperidine by ammonia, it is concluded that the decomposition of ammoniacal salts by fixed bases is a phenomenon of heterogeneous dissociation.—On a

new derivative of phenylisindazol, obtained by the action of salicylic aldehyde upon phenylhydrazine, by M. H. Causse.—Action of tannin upon some alkaloids, by M. Oechsner de Coninck. Pyridine and piperidine can be readily distinguished by their reactions with an aqueous solution of tannin.—On the use of cryoscopic methods in the analysis of milk, by MM. Bordas and Génin. This is a reply to a note on the same subject, by M. Winter. The results obtained, although fairly constant, are opposed to the exclusive use of the freezing-point method for milk; its only value is as a method of control.—On the carbohydrates remaining in beer, by M. P. Petit.—On oxidation and the decolourisation of wines, by M. V. Martinand. This oxidation can take place sometimes in the absence of an oxydase, if the wine is acid.—Mineralogical study of the action of volcanic sulphuretted fumerolles upon serpentine, by M. A. Lacroix. The minerals observed include epsomite, marcasite, melanterite, and copiapite, all directly attributable to the action of the sulphuric acid and hydrogen sulphide upon the serpentine.—The geological constitution of the mountains about the sources of the Bléone and the Var, by M. Kilian.—Parallelism between the cretaceous beds of Mondégo and Lisbon, by M. Paul Choffat.—Note on the treatment of articular diseases by electricity, by M. Danion.—Note on the numerical relations between the masses of the planets, by M. Delauney.

DIARY OF SOCIETIES.

THURSDAY, MARCH 18.

ROYAL SOCIETY, at 4.30.—Cultural Evolution of the Cyclamen: W. T. Thiselton-Dyer.—On the Conditions which render Absolute the Readings of the Mercurial Thermometer: S. A. Sworn.—Experiments on the Flame Spectrum of Carbon Monoxide: Prof. Hartley, F.R.S.

ROYAL INSTITUTION, at 3.—Greek History and Extant Monuments: Prof. Percy Gardner.

LINNEAN SOCIETY, at 8.—Further Observations on Stipules: Right Hon. Sir John Lubbock, Bart., M.P., F.R.S.—On the Origin of Transfusion-tissue in the Leaves of Gymnospermous Plants: W. C. Worsdell.

CHEMICAL SOCIETY, at 8.—On the Atomic Weight of Carbon: Dr. Alexander Scott.—On a New Series of Mixed Sulphates of the Vitriol Group: Dr. Alexander Scott.—The Action of Alkylhaloids on Aldoximes and Ketoximes: Wyndham R. Dunstan, F.R.S., and Ernest Goulding.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Fifth "James Forrest" Lecture—Bacteriology: Dr. G. Sims Woodhead.

SANITARY INSTITUTE, at 8.—Infectious Diseases and Methods of Disinfection: Dr. H. R. Kenwood.

CAMERA CLUB, at 8.15.—Geographical Pictures: Dr. H. R. Mill.

FRIDAY, MARCH 19.

ROYAL INSTITUTION, at 9.—Greek and Latin Palæography: Sir Edward Maunde Thompson.

EPIDEMIOLOGICAL SOCIETY, at 8.—The Prevention of Tuberculosis: Dr. James Niven.

SATURDAY, MARCH 20.

ROYAL INSTITUTION, at 3.—Electricity and Electrical Vibrations: Lord Rayleigh, F.R.S.

MONDAY, MARCH 22.

IMPERIAL INSTITUTE, at 8.30.—The Timber Supply of the British Empire: Dr. W. Schlich.

SOCIETY OF ARTS, at 4.30.—Alloys: Prof. W. Chandler Roberts-Austen, C.B., F.R.S.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The North Polar Problem: The President.

SANITARY INSTITUTE, at 8.—Water Supply, Drinking Water, Pollution of Water: Prof. W. H. Corfield.

CAMERA CLUB, at 8.15.—A Run through Portugal and Madeira, to the Great River Amazon: W. Wethered.

TUESDAY, MARCH 23.

ROYAL INSTITUTION, at 3.—Animal Electricity: Prof. A. D. Waller, F.R.S.

ROYAL HORTICULTURAL SOCIETY, at 1.—Fruit-bud Transference.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be discussed: The Mond Gas-Producer Plant and its Application: H. A. Humphrey.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Polar Exploration: A. Montefiore Brice.

ROYAL VICTORIA HALL, at 8.30.—Marine Food Fishes: Gilbert C. Bourne.

WEDNESDAY, MARCH 24.

SOCIETY OF ARTS, at 8.—The Transmission of Power by Alternating Electric Currents: W. B. Esson.

GEOLOGICAL SOCIETY, at 8.

INSTITUTION OF CIVIL ENGINEERS, at 4.—Dr. G. Sims Woodhead will repeat the Fifth "James Forrest" Lecture on Bacteriology.

THURSDAY, MARCH 25.

ROYAL SOCIETY, at 4.30.—Meeting for Discussion. *Subject*: The Chemical Constitution of the Stars, introduced by J. Norman Lockyer, C.B., F.R.S., with a Communication "On the Chemistry of the Hottest Stars."

ROYAL INSTITUTION, at 3.—The Relation of Geology to History: Prof. W. Boyd Dawkins, F.R.S.

SOCIETY OF ARTS (Imperial Institute), at 8.—The Cultivation and Manufacture of Rhea Fibre: Thomas Barraclough.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—On some Repairs to the South American Company's Cable off Cape Verde, 1893 and 1895: H. Benest. (Continuation of Discussion.)

CHEMICAL SOCIETY, at 8.—The Pasteur Memorial Lecture: Prof. P. F. Frankland, F.R.S.

CAMERA CLUB, at 8.15.—From Mont Blanc to the Matterhorn: Lamond Howie.

FRIDAY, MARCH 26.

ROYAL INSTITUTION, at 9.—Early Man in Scotland: Sir William Turner, F.R.S.

PHYSICAL SOCIETY, at 5.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Re-signalling of the Liverpool Street Terminus of the Great Eastern Railway: W. J. Griffiths.

SATURDAY, MARCH 27.

ROYAL INSTITUTION, at 3.—Electricity and Electrical Vibrations: Lord Rayleigh, F.R.S.

ROYAL BOTANIC SOCIETY, at 4.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.
